Another interesting technology is the use of reversed-phase packings designed with an external hydrophilic surface. These packings, called internal-surface reversed-phase or restricted access packings,$^{45,46}$ are designed for the chromatographic analysis of drugs directly from blood plasma. The internal hydrophobic surface on the inside of the pores of the packing is responsible for the retention of drugs and metabolites. However, proteins interact only with the external hydrophilic surface and are excluded from the internal surface owing to their size. The binding of proteins to the external hydrophilic surface is weak and they are eluted without difficulty. On classical reversed-phase packings, proteins would stick to the external surface and rapidly clog the column. Therefore, improved column life is possible with restricted-access packings, but the internal surface can still become contaminated with lower-molecular-weight contaminants that can penetrate the pores.

In one approach,$^{45}$ a hydrophobic tripeptide is bonded to a diol-derivatized silica with a standard pore size. Subsequently, the peptide is clipped off the external surface of the packing with an enzyme that is unable to penetrate the smaller pores of the packing. Consequently, the external surface becomes hydrophilic, showing little interaction with serum proteins, while the internal surface is responsible for the reversed-phase retention of the smaller analytes. In the second approach,$^{46}$ a standard hydrophobic surface is created first via a standard silanization technique. Then, the packing is immersed in an aqueous acid. Surface tension does not permit the penetration of the aqueous acid into the hydrophobic pores, but the coating external to the pores of the packing is cleaved off. In the final step, the external surface is coated with a diol silane to prevent the interaction of proteins with the external surface.

In order to create an analog to lipid membranes for separation with molecular recognition, a comb-shaped bonded phase was devised.$^{47}$ The ligand was synthesized by telomerization of 3-thiopropytrimethoxysilane and octadecylacrylate and subsequently attached to the surface of silica. This bonded phase showed a remarkable temperature dependence of the retention factor and of the relative retention for aromatic hydrocarbons, indicating a phase transition of the immobilized ligand.

![Figure 5](image-url) IAM. The phase designated etherIAM,PC$^{30}/C^3$ by Ong et al.$^{38}$ is shown.

3.5 Properties of Bonded Phases

In this section, the specific properties of bonded phases and their use will be examined. Since the largest use of columns is for reversed-phase chromatography, this application area will be discussed first. Included in the discussion is the description of evaluation techniques for reversed-phase packings and the reproducibility of the preparation technique. Then we will discuss normal phase chromatography, followed by a brief review of other application areas.
3.5.1 Phases for Reversed-Phase Chromatography

The most commonly used phase for reversed-phase chromatography is the C\textsubscript{18} phase, in which an octadecylsilane (12) is attached to the silica. This is followed by the closely related C\textsubscript{8} phase which uses an octylsilane (13).

The retention of hydrophobic analytes in a given mobile phase is generally larger for a C\textsubscript{18} phase than for a C\textsubscript{8} phase, and generally proportional to the ratio of the amount of stationary phase to the mobile phase volume, similar to the phase ratio discussed earlier. Therefore, C\textsubscript{18} phases with a low surface coverage may exhibit retention properties similar to highly coated C\textsubscript{8} phases. For more polar analytes, the situation is more complicated: polar analytes may penetrate the bonded-phase layer only partially and therefore interact with only part of the bonded phase. In such a case, the retentivity of a C\textsubscript{18} and a C\textsubscript{8} phase may be very similar. Conversely, polar, especially basic analytes may be more strongly retained on packing materials with a high activity of the silanol groups. Therefore, the assumption that a C\textsubscript{18} packing exhibits more retention than a C\textsubscript{8} packing should be treated with caution.

Most C\textsubscript{18} and C\textsubscript{8} packings are based on silica with a pore size of around 100 Å (1 Å = 10\textsuperscript{-10} m). This pore size is marginal for peptide separations and too small for the separation of proteins. For this application area, packings with a pore size of 300–500 Å have been designed. Commonly, a gradient is used from 5% or 10% acetonitrile to a high percentage of acetonitrile, with an acidic buffer based on trifluoroacetic acid. Some other mobile phase options are available as well, but are only rarely used.

Reversed-phase packings with an incorporated polar functional group are closely related to the classical C\textsubscript{8} and C\textsubscript{18} phases. Phases in this group are SymmetryShield\textsuperscript{™} RP\textsubscript{8} (14) and SymmetryShield\textsuperscript{™} RP\textsubscript{18} from Waters, USA\textsuperscript{,50} Discovery\textsuperscript{™} RP-AmideC16 and its predecessor Supelcosil\textsuperscript{™} ABZ + (15) from Supelco, USA\textsuperscript{,51,52} and the Prism\textsuperscript{™} column from Keystone Scientific, USA\textsuperscript{,53}. The common factor among these phases is the fact that a polar functional group is incorporated into the hydrophobic bonded phase.

The incorporation of the polar functional group adds several advantageous properties to these packings. Most important, it suppresses the influence of silanol groups on the retention of basic analytes much more effectively than any other approach used. As a consequence, excellent peak shapes are obtained for basic compounds that exhibit tailing even on the best C\textsubscript{8} or C\textsubscript{18} packings. Another consequence of the suppression of the influence of silanols is the fact that phases with an incorporated polar functional group exhibit different selectivities from classical C\textsubscript{8} and C\textsubscript{18} packings, while the overall retentivity is similar to comparable C\textsubscript{8} or C\textsubscript{18} packings. The third advantage of these phases is the fact that they do not exhibit “hydrophobic collapse” as do highly coated classical phases. Hydrophobic collapse is a the name given to a phenomenon observed for the most deactivated reversed-phase packings in highly aqueous mobile phases: suddenly the retentivity of the packing is lost when the flow through the column is stopped for a moment. This occurs because the polar mobile phase is driven out of the pores of a hydrophobic packing owing to surface tension effects\textsuperscript{,54} specifically the high contact angle between water and the hydrophobic surface. Since the incorporated polar functional group reduces the contact angle with water and makes the surface more “wettable”, this phenomenon does not occur.

3.5.2 Evaluation Techniques for Reversed-phase Packings

Reversed-phase packings exhibit a wide range of retention properties that vary with the nature of the analyte. This has created significant interest in a universal characterization of the retention properties of reversed-phase packings. A better understanding of the selectivity of reversed-phase packings would help a user in the selection of a packing.

Several column tests are available that characterize relevant properties of reversed-phase packings. A test developed by Sander and Wise\textsuperscript{,34,35} is designed to characterize the shape selectivity of a packing, which depends
on the chain spacing of the bonded phase. The selectivity for the shape of the analytes is especially important in the analysis of polynuclear aromatic hydrocarbons. The test mixture, which is available as a National Institute of Standards and Technology (NIST) standard reference material, comprises three aromatic hydrocarbons, BaP, phenanthrene (PhPh), and TBN. The elution order of these compounds depends on the coating level, and thus the chain spacing, of a C18 bonded phase. For packings with a surface coverage under 3.5 µmol m⁻², the elution order is BaP < PhPh < TBN. These packings are considered to be monomeric packings. For polymeric packings with a higher surface coverage, the elution order is PhPh < TBN < BaP. The relative retention between TBN and BaP has been found to vary from 0.6 to 2.2 for a range of commercial packings. This test is useful for the characterization of the density of the surface coating of a packing and can be used to predict the properties of a packing for the separation of aromatic hydrocarbons.

Tests developed by Engelhardt and co-workers (55–57) are primarily designed to test the hydrophobicity and the silanol activity of a reversed-phase packing. The test mixture varied slightly over the history of the test, but consists fundamentally of hydrophobic probes, toluene and ethylbenzene, a mildly acidic probe, phenol, and basic probes such as aniline, N,N-dimethylaniline or toluidines. The mobile phase is a mixture of 49% methanol and 51% water (w/w). The relative retention between the basic samples and toluene can be used to assess the silanol activity of a packing. High values indicate a high silanol activity. In addition, an increase in tailing for the basic compounds is an indicator of silanol activity. Furthermore, the co-elution of the toluidine isomers is characteristic of a silica with low silanol activity.

**Figure 6** Selectivity chart of commercial C₈ and C₁₈ packings. The x-axis is the natural logarithm of the hydrophobicity of the packing, measured by the retention factor of acenaphthene. The y-axis is the natural logarithm of the silanol activity of the packing, measured by the relative retention of amitriptyline and acenaphthene at pH 7.00. (The graph is based on data provided by B.A. Alden, Waters Corp.)
A derivative of the Engelhardt test has been developed by Neue and Serowik et al.\(^\text{2,58,59}\) The principle of both tests is similar: a mixture of neutral, acidic and basic analytes is used to characterize the overall properties of a packing. The hydrophobicity of a packing is measured via the retention of an aromatic hydrocarbon such as toluene or acenaphthene and the silanol activity is measured using basic analytes such as tricyclic antidepressants or propranolol. These basic analytes exhibit an especially strong interaction with silanols, which makes it possible to run this test in a buffered mobile phase consisting of 65.0% methanol and 35.0% of a 20 mM phosphate buffer at pH 7.00. This test, which originally was designed to test the batch-to-batch reproducibility of the same packing, can also be used to classify different packings. In Figure 6 the results are shown for a multitude of packings. The hydrophobicity is obtained from the retention factor of acenaphthene and the silanol activity is derived from the relative retention of amitriptyline and acenaphthene. Packings with a low hydrophobicity are found on the left side of the graph, packings with a high hydrophobicity are found on the right side. Packings with a low silanol activity are found on the bottom of the chart, unendcapped packings with a high silanophilic activity on the right side. Packings with a low silanol activity are found on the bottom of the chart, unendcapped packings with a high silanol activity on the top of the chart. Note that both axes are logarithmic! C\(_8\) packings are commonly found on the left side of the chart and C\(_{18}\) packings on the right side. Generally, packings based on high-purity silicas with a high coating level cluster together in the lower part of the chart. A line can be drawn between three different packings that are based on the same silica but differ from each other in the C\(_{18}\) coating: YMC J’Sphere L80, YMC J’Sphere M80 and YMC J’Sphere H80. This demonstrates the general validity of the chart: at low coating (YMC J’Sphere L80), more silanols are available for interaction, resulting in a high hydrophilic activity together with a low hydrophobicity; at high coating (YMC J’Sphere H80), the silanol activity decreases and the hydrophobicity increases. Packings with an incorporated polar functionality are found at the very bottom of the chart, indicating that this design of the bonded phase indeed reduces the influence of silanols on the retention of reversed-phase packings.

Similar tests were developed by Tanaka et al.\(^\text{60}\) He proposed use of the retention factor of amylobenzenz in 80% methanol as a measure of the number of alkyl chains bonded to the silica and the relative retention between amylobenzene and butylbenzene as a measure of the hydrophobicity of a packing. In analogy to the procedure used by Sander and Wise, the relative retention between triphenylene and \(\text{o-terphenyl}\) is used as a measure of the steric selectivity of a packing. The relative retention between caffeine and phenol measured in 30% methanol/water is used as a measure of the hydrogen bonding capacity of the packing, which depends on the amount of underivatized silanols on the surface of the packing. In addition, the relative retention of benzylamine and phenol is measured at acidic and neutral pH with 30% methanol, as a measure of the ion-exchange sites at both pH values. Since the silanol sites are also the ion-exchange sites, one would expect a reasonable correlation between the relative retention of caffeine/phenol and the relative retention of benzylamine/phenol at neutral pH. However, a buffered mobile phase provides a more controlled environment that is independent of the state of the surface silanols left from the prior history of the packing. The differences between the amount of ion exchange measured at acidic pH and at neutral pH is a measure of the acidity of the surface silanols and is therefore related to the temperature history and the purity of the silica.

The evaluation techniques discussed above have all been used to characterize the retention properties of different packings, but a large scale comparison between the different methods is not yet available. However, smaller scale comparisons reveal a reasonable correlation between some aspects of the different tests. The test developed by Neue and Serowik was originally designed as a batch-to-batch reproducibility test. Therefore, its reliability, reproducibility and simplicity are notable. Tanaka’s procedure involves several separate tests, which increases the complexity, but allows the measurement of features that escape the Neue/Serowik test. The main strengths of the Engelhardt test are the selection of test compounds that are readily available to anybody, and a very large body of data.

### 3.5.3 Batch-to-batch Reproducibility

An important aspect of a packing is the reproducibility of the separations obtained when a new column packed with the same type of packing is used. In general, the reproducibility is impeccable if the same batch of packing is used. However, when different preparations of the same packing are compared with each other, differences in the retention properties can be observed. From some manufacturers, a sufficient part of the specifications of the packing is available to allow a comparison of the reproducibility. A key element is the surface coverage of a packing, which extends beyond the carbon content. For packings for which this information is not available, the user can get an estimate from the specification of the carbon content and the specific surface area, using Equation (4). Examples of the allowable ranges of surface coverage (and therefore reproducibility) are 2.75–3.75 \(\mu\text{mol m}^{-2}\) for Luna\textsuperscript{™} C\(_{18}(2)\) (Phenomenex, USA) or a range of 3.09–3.31 for Symmetry\textsuperscript{™} C\(_{18}\) (Waters Corp., USA). Unfortunately, the information given by
LIQUID CHROMATOGRAPHY

Figure 7 Batch-to-batch reproducibility of three commercial packings. The relative standard deviations (RSDs) for two characteristic parameters are shown: in the foreground, the batch-to-batch reproducibility of the relative retention between two neutral compounds; in the background, the same data are shown for a pair of basic analyte and neutral analyte.

many manufacturers is insufficient to make a judgement on the reproducibility of a packing. However, the characterization tools described in the last section can also be used to test the reproducibility of the preparation of a packing, if proper controls of the mobile-phase composition and column temperature are implemented. The best way to assess the reproducibility of a packing is to look at the reproducibility of both a compound pair of very similar properties and a compound pair of widely different properties. An example of the first group is the relative retention of neutral, hydrophobic analytes, such as acenaphthene and toluene. An example of the second group is the relative retention between a basic analyte, such as amitriptyline and a neutral analyte, such as acenaphthene. These data are shown in Figure 7 for three commercial packings. The data were collected over a period of several years.

3.5.4 Other Reversed-phase Packings

Owing to the broad range of available properties, most reversed-phase applications are accomplished with either C18 or C8 columns. Nevertheless, other types of stationary phases have found their niche. The most popular types are phenyl columns (16) and cyano columns (17), whose structures are shown below.

There are several possibilities for the link between the phenyl group and the silicon attached to the surface. Unfortunately, the information given by manufacturers of phenyl columns is often too vague to establish the way in which a particular phenyl column was designed. For some of the more popular phenyl phases, the structure is known: Nova-Pak Phenyl™ (Waters Corp., USA) is based on a propylphenyl ligand, Zorbax Phenyl™ packings (Hewlett-Packard, USA) use an ethylphenyl ligand, and μBondapak Phenyl™ (Waters Corp., USA) employs an α-methylphenylethyl ligand. Selectivity differences between phenyl phases and classical C8 and C18 phases have been observed, but it is not clear if they can be attributed to the phenyl group or simply to a difference in surface coverage and chain density compared with C8 and C18 packings. Before the introduction of the packings with an incorporated polar functional group, phenyl packings were the tool used by chromatographers to achieve a different selectivity for the separation.

In the early years of chromatography, cyano phases were often employed when different selectivities were sought. However, experience has driven most users away from reversed-phase applications of cyano columns. The hydrolytic stability is about three orders of magnitude lower for CN phases compared with C18 phases. In addition, the mechanical stability of CN columns is significantly inferior to other reversed-phase columns. Owing to the multitude of better options, reversed-phase applications of CN columns have been declining.

Very short chains are commercially available as well, but the nomenclature of the designation may not be clear. A phase designated C3 by one manufacturer may be identical to a C1 phase of another manufacturer and the bonded phase is based on a trimethylsilane. These very short chains have a better hydrolytic and mechanical stability than CN phases and can be used with advantage. Short chains, commonly C4 (18), are used for the reversed-phase separation of proteins. In this case, the pore size of the silica is larger, typically 300 Å or 500 Å.

3.5.5 Bonded Phases for Other Types of Chromatography

While the predominant use of bonded phases is in the world of reversed-phase chromatography, other application areas should not be overlooked. A few phases, commonly abbreviated as cyano (19), amino (20), diol (21), and nitro (22) are used in normal phase
chromatography. The diol and amino phases are mostly utilized in highly specific application areas.

Most polar bonded phases are based on trifunctional silanes. On one hand, this adds to the hydrolytic stability, on the other hand the influence of a large population of silanols on the separation should be considered.

Compared with silica columns, bonded phases are less sensitive to the water content of the mobile phase, which improves the reproducibility of a normal-phase separation. In addition, significantly different selectivities can be achieved. However, manipulation of the selectivity of a separation is rarely a problem in normal-phase chromatography, since a wide range of mobile phase options is available.\(^{(2)}\)

Cyano packings are the least polar of the packings used in normal-phase chromatography. While there is little concern about the hydrolytic stability of CN phases in normal-phase chromatography, care should still be exercised with respect to the mechanical stability, especially when solvents of intermediate polarity are used to wash the columns in a clean-up procedure.

Nitro phases, or better nitrophenyl phases, have been used in the normal-phase separation of aromatic hydrocarbons. The separation mechanism is influenced by the formation of \(\pi-\pi\) bonds between the analytes and the bonded phase. The consequence is a group separation of the aromatic hydrocarbons based on the number of rings. Nitro phases with more than one nitro group per ring have also been designed. This increases the strength of the \(\pi-\pi\) interaction. Occasionally, a reversed-phase application of nitro phase is found as well.

While applications of diol columns in normal phase chromatography are comparatively rare, this stationary phase nevertheless presents an interesting polar alternative to silica, since it is less sensitive than silica to the water content of the mobile phase. However, the primary application area of diol columns is in aqueous size-exclusion chromatography, especially of proteins. High coating levels largely suppress the interaction of proteins with the underlying silica, provided a mobile phase with a salt concentration between 0.1 and 0.5 mol L\(^{-1}\) is used. At lower salt concentrations, the influence of residual silanols on retention becomes apparent, at higher salt concentration, hydrophobic interactions distort the separation. Figure 8 shows a gel filtration separation of protein standards using a diol column. Another, less commonly used application area of diol columns is hydrophilic interaction chromatography, using acetonitrile–water mixtures with a high acetonitrile content for the separation of very polar compounds.

In normal-phase chromatography, amino columns are another interesting alternative to underivatized silica. A special application is related to the main application of nitrophenyl packings: the class separation of aromatic hydrocarbons. The separation patterns are similar for both columns: in both cases, the analytes are separated into groups of common ring size. However, the primary application area for amino columns is in hydrophilic interaction chromatography for the separation of carbohydrates (Figure 9). The separation mechanism\(^{(61)}\) for the sugar separations is a partitioning mechanism between a mobile phase with a low water content and the stationary phase with an enriched water content. The main advantage of the amino column over other polar packings (such as diol) is the fact that amino columns do not separate the sugar anomers, while other polar phases do. The reason for this is the fact that the local basic environment promotes the interconversion of the anomers during the chromatographic run. Therefore, all sugars elute as single, albeit somewhat broad peaks.

It should be noted though that silica-based amino phases
LIQUID CHROMATOGRAPHY

are not completely stable in an aqueous environment: the high concentration of amino groups in the pores of the packing creates a high pH value, which leads to a partial dissolution of the silica and the bonded phase. This occurs until a sufficient number of acidic silanol groups is available to reduce the local pH. Therefore, amino columns for the separation of sugars are commonly pretreated to reach a stable arrangement.

Another group of stationary phases based on silica are the ion exchangers (23) and (24). Both strong cation and strong anion exchangers are commercially available. The anion exchanger can be prepared by direct synthesis or by a secondary reaction of a dimethylaminopropyl silane bonded phase with a methylating reagent. Two types of cation exchangers are possible: one is based on a purely aliphatic chain, the other is based on an aromatic sulfonic acid. Similarly, quaternary amines based on an aromatic core group in the bonded phase are possible as well.

The application literature is not as extensive as the application literature using classical ion exchangers based on an organic backbone. This is mostly due to the limitations in the pH range imposed by the silica backbone. In addition, ion-pair chromatography(62) based on well-defined reversed-phase packings has become a more versatile substitute for ion-exchange separations of small molecules.

However, ion-exchange chromatography remains one of the primary tools in the separation of biomacromolecules. The special phases for this application fall into the category of coated phases and are discussed in the next section.

4 COATED PHASES

In this section, the properties of silica-based coated phases are discussed. The coating consists of a physically adsorbed or chemically bonded and/or crosslinked polymer layer that modifies the adsorption properties of the substrate by superimposing its own properties. Properly executed, it should be possible to combine the advantageous properties of the coating with the mechanical strength of the silica. Note that many of the stationary phases discussed in this section can be prepared on inorganic substrates other than silica. The advantage of other substrates lies in the improved pH stability compared with silica: silica dissolves with an appreciable rate at pH values exceeding 9 at room temperature, therefore substrates like alumina, titania, or zirconia have marked advantages. Nevertheless, most work has been done using silica as the base material.

In general, very few phases with a polymeric surface layer have been commercially successful. Prevailing applications include packings designed for the chromatography of macromolecules like proteins(63–65) and packings for special applications, e.g. ion chromatography. The reason for this limited success is the inferior mass-transfer properties of coated phases for small molecules, which is due to the fact that the polymeric layer can be at least partially penetrated by small molecules and that diffusion in the polymeric layer is slow. This feature is shared with fully organic packings. The problem either becomes irrelevant, if no packing with equivalent selectivity and good mass transfer is available, or disappears, if the molecular weight of the analytes is sufficiently large, as is the case for proteins.

Many different polymers have been immobilized on silica. Petro and Berek(66) list some 80 different types of polymer–silica combination. The polymeric layer may be bonded to the surface, or cross-linking may keep it in place without attachment to the surface. If the polymer is not generated in situ, an important consideration in the preparation is the access of the polymer to the pores of the packing. Therefore, four different preparation procedures for polymer-coated packings can be differentiated:

1. polymerization or polycondensation of monomers without bonding to the surface
2. polymerization or polycondensation of monomers with bonding to the surface
3. immobilization of prepolymers without attachment to the surface

The application literature is not as extensive as the application literature using classical ion exchangers based on an organic backbone. This is mostly due to the limitations in the pH range imposed by the silica backbone. In addition, ion-pair chromatography(62) based on well-defined reversed-phase packings has become a more versatile substitute for ion-exchange separations of small molecules.

However, ion-exchange chromatography remains one of the primary tools in the separation of biomacromolecules. The special phases for this application fall into the category of coated phases and are discussed in the next section.
4. immobilization of prepolymers with attachment to the surface.

In the following, these different approaches are described briefly.

4.1 Preparation Techniques for Coated Phases

4.1.1 Polymerization or Polycondensation of Monomers Without Bonding to the Surface

In this approach, the monomers are first coated into the pores or onto the surface of the silica. Then, the polymerization is initiated. Since it is not difficult to generate a uniform coating of the surface with the monomer(s), such a process should then result in a uniform polymeric coating of the packing as well. However, results obtained with this technique\(^7\) were rather disappointing, when small analytes were investigated: for thin layers, the silica matrix was poorly shielded by the polymeric layer and influenced the retention of basic analytes, while thick layers resulted in an inferior mass transfer and broad peaks for small analytes. The results are shown in Table 2. The influence of silanols on the retention of basic analytes can be measured by the relative retention between propranolol and acenaphthene; as the coating level increases, the relative retention becomes smaller, i.e. the relative influence of silanols on the retention drops. However, the mass-transfer term, measured with toluene as sample, increases as the coating level increases. On a C\(_{18}\) column based on the same silica, the mass-transfer term for toluene was only 3 ms. This clearly exemplifies the general problem of polymeric coatings on silica or other inorganics: polymeric coatings result in inferior mass transfer and thus inferior plate counts for small molecules.

4.1.2 Polymerization or Polycondensation of Monomers with Bonding to the Surface

When at least one of the monomers used in the polymerization is attached to the surface, better adhesion of the resulting polymer to the surface is expected and a more conformal coating should be achievable. Packings prepared using this approach have been reported by Engelhardt and co-workers\(^7\) and are commercially available under the trade name Polyencap\(^\text{a}\) (Bischoff GmbH, Germany). The packings are prepared by first bonding vinylsilane to the silica surface, then coating the resulting surface with an acrylate monomer, which is then polymerized along the surface. Generally, good mass-transfer properties have been reported for these packings, but owing to the low coreactivity of vinylsilane with the monomers, a clear picture of the nature of the resulting surface is not available. In this procedure, only 50–80\% of the monomer was incorporated in the packing and chemically anchored to the surface, demonstrating the low coreactivity of the vinylsilane with the monomers.

The method used for the preparation of a range of commercial silica derivatives used for the separation of biopolymers (PolyLC, USA) is related to this approach. In this procedure\(^7\) \(5\times\)\(125\) silica of the correct pore size is first derivatized with aminopropyltriethoxysilane in toluene. The resulting amino-bonded phase is then treated with poly(succinimide) at room temperature in tetrahydrofuran (THF). This phase can then be used to prepare a range of derivatives, e.g. a poly(aspartic acid) derivative by reaction with \(\beta\)-alanine as a weak cation exchanger, a poly(2-aminoethyl aspartamide) derivative from ethylenediamine as a weak anion exchanger, poly(alkyl aspartamide) derivatives for hydrophobic interaction chromatography\(^7\), a poly(2-sulfoethyl aspartamide) derived from taurine as a strong cation exchanger\(^7\), and a poly(2-hydroxyethyl aspartamide) derivative for hydrophilic interaction chromatography\(^7\). These packings have been used extensively in the separation of proteins and peptides. While data for the mass-transfer behavior of these packings for small molecules are not available, the quality of the gradient separations of proteins and peptides is impressive.

Another successful group of packings in this category is the group of “tentacle” ion exchangers (Merck, Germany) which are also employed in the chromatography of biopolymers\(^7\). The difference between classical ion exchangers and the tentacle type is the location of the ion-exchange groups on the packing. For classical ion exchangers, the ion-exchange groups are located on the internal surface of the packing. For tentacle ion exchangers, they are located on linear polymer chains grafted to the support surface. The free access to the ion-exchange groups improves the interaction with biopolymers, while avoiding distortions of the three-dimensional conformation of the analytes. Consequently, significantly different selectivities have been observed compared with classical ion exchangers and improved chromatographic performance has been reported. However, as for any other packing for the

chromatography of biopolymers, a quantitative measurement of the mass-transfer properties of the tentacle packings is not available, which makes an objective judgement of the quality of the packing difficult.

### 4.1.3 Immobilization of Prepolymers Without Attachment to the Surface

In the third approach, a low-molecular-weight polymer is coated onto the surface and then immobilized through chain extension or crosslinking. Examples of this approach have been pursued by Schomburg et al.\(^{(76)}\) Of course, whenever procedures are used that can generate a nonbonded coating on silica, other inorganics can be substituted with advantage. Poly(butadiene)-coated alumina exhibits an improved pH stability relative to silica-based sorbents. However, while no concrete data on column efficiency or mass transfer are available in the literature, a decrease in column performance relative to classical phases has often been observed. However, this is not an impediment for specific applications. Schomburg’s group also coated silica with a copolymer of butadiene and maleic acid to create a cation exchanger.\(^{(77)}\) The most popular application of this packing is the simultaneous separation of alkali and alkaline earth ions in a single isocratic chromatographic run (Figure 10), which is not achievable with any other packing.

The coating of silica with polybutadiene\(^{(78)}\) or with poly(methyloctylsiloxane)\(^{(79)}\) has been investigated in detail. In the latter study, it was demonstrated that the surface area decreases linearly with the specific loading of polymer onto the silica and that this behavior is inconsistent with a uniform film coating the surface of the packing. In the former study, a broad arsenal of tools ranging from nitrogen sorption to solid-state NMR was employed to demonstrate the same feature: “polybutadiene coatings on silica do not result in a homogeneous polymer film but in an inhomogeneous loading...”, and “an increasing polymer loading leads to increasingly filled pores instead of a thicker polymer film”.\(^{(80)}\) Until now, the problem of generating a uniform polymeric film on the surface of a sorbent without bonding to the surface remains unsolved.

For the separation of proteins, polyethyleneimine was coated onto silica and crosslinked.\(^{(80)}\) This durable anion exchanger has been successfully employed in the separation of many biopolymers. It could be argued that the polyethyleneimine is attached to the surface via an ion-exchange interaction and that this packing belongs to the category discussed in the next paragraph.

Both techniques have been used to coat small nonporous silica spheres as well. The principle behind this approach is to take advantage of the more rapid mass transfer of nonporous particles for the fast separation of macromolecules. For example, polybutadiene was coated onto nonporous silica spheres of 1.7 \(\mu\)m diameter.\(^{(81)}\) The small particle diameter together with the fact that the packing was nonporous allowed for rapid gradient separations of peptides. In an earlier publication,\(^{(82)}\) the coating of nonporous silica spheres with polyethyleneimine was investigated. Very rapid separations of proteins and nucleotides were obtained.

### 4.1.4 Immobilization of Prepolymers with Attachment to the Surface

An example of the immobilization of a prepolymer with attachment to the surface of silica has been published by Petro et al.\(^{(83)}\) The purpose for the design of such a phase was the size-exclusion chromatography of proteins. The silica is first reacted with \(\gamma\)-glycidoxypropyltriethoxysilane in dry toluene. The resulting product is then further derivatized with aqueous solutions of dextran or ethylenediamine derivatives of dextran at various \(pH\) values in water. Unfortunately, a significant amount of interaction with silanols remained on the packing, requiring still higher salt concentrations (0.25 M) to elute proteins in size-exclusion mode.

In another example,\(^{(84)}\) polyvinylpyrrolidone was coated onto large pore silicas. First, a copolymer of vinylmethylidioxyxilane and vinylpyrrolidone was created. Then this polymer was attached to the silicas via the active silane groups. Finally, the material was endcapped using a standard process. Both size-exclusion chromatography and hydrophobic interaction chromatography of

proteins were possible with this packing. However, the packing loses attractiveness owing to the necessity of following through with the hydrolytically weak endcapping step.

4.2 Properties of Coated Phases

Most investigations of silica-based coated phases have been focused on the preparation of materials for the separation of biomolecules. This is largely due to the fact that most phases in this category suffer from restricted mass transfer for small molecules and therefore inferior column performance. The most promising category for small molecules appears to be the second category, where the preparation involves a polymeric surface coating from monomers with a known attachment to the surface.

For proteins and other large molecules, the same principle has also yielded the most promising results. The long-standing success of the phases described by Alpert (63–65,74) as well as the newer success of the tentacle phases support this approach. Nevertheless, one needs to differentiate between reality and marketing claims. In a fundamental study, Ratnayake and Regnier (85) studied the protein binding capacity of ion exchangers prepared by the second principle. They concluded that the mechanism of adsorption is similar between tentacle-type ion exchangers and surface-bound ion exchangers. Among other things, the Z-number, which is a characteristic value for the number of the interaction sites between ion exchanger and analyte, was similar for both types of sorbents. The increased capacity of tentacle-type ion exchangers compared with surface-bound ion exchangers is therefore simply due to an increased number of available exchange sites owing to the larger surface area of the tentacle-type packings.

The other issue for the separation of macromolecules is the plate count achievable with different packings. Unfortunately, the techniques that allow a determination of the plate count under gradient conditions (3) have not yet been applied to these packings, and therefore an objective comparison is not yet possible. It might be expected that the situation is similar to the situation for small molecules; nonporous packings exhibit a higher plate-count performance, but a lower capacity than porous packings. However, the differences are expected to be much smaller owing to the necessity of taking into account larger pore sizes for macromolecules compared with smaller molecules. With respect to the performance of coated phases compared with classical bonded phases, a lesser sensitivity of the HETP for macromolecules on the details of the surface coating can be expected. The success of the Alpert phases and the tentacle phases supports this expectation.

5 SUMMARY

The classical derivatization of silica has become the main tool for the preparation of stationary phases for classical HPLC, i.e. the separation of small molecules. The influence of the properties of the silica and the stationary phase are well understood. Nevertheless, progress continues to be made. The success in the 1990s of high-purity silica as the carrier of bonded phases is the dominant example. On a smaller scale, bonded phases for reversed-phase chromatography with incorporated polar functionality are now more widely used owing to their improved peak shape compared with classical packings. The newest development for the analysis of small molecules are the continuous rod structures, whose success will be determined in the future.

Until now, silica-based stationary phases have played a more limited role in the HPLC separations of biopolymers. Some innovative approaches have been applied and progress has been made, but silica-based phases are only one of many tools used in the separation of biomolecules. The more promising approaches use a polymeric coating of the silica to combine the benefits of the strength of silica with the biocompatibility of the polymeric coating.

In addition to the information presented in this article, the literature contains supplemental or related specific information. Dorsey et al. (86) review fundamental developments in the LC literature from October 1995 to October 1997. Leonard (87) gives a general review of new packing materials for protein chromatography, including polymer-based and silica-based packings. Interested readers are referred to these review articles.

Supercritical fluid chromatography (SFC) employs fluids that are raised above their critical pressure ($P_c$) and critical temperature ($T_c$) as mobile phases. Carbon dioxide, $CO_2$, is the supercritical fluid most commonly used as a mobile phase for SFC. It is capable of solvating mostly nonpolar analytes. Cosolvents, such as methanol and acetonitrile, are added to increase the polarity of the analytes that can be analyzed by SFC. SFC is most commonly practiced using a normal-phase retention mechanism. In other words, the stationary phase is typically more polar than the mobile phase and the retention order is in increasing order of polarity. The advantages of SFC over liquid chromatography (LC) include higher efficiency separations and faster speed of analysis. The advantage that SFC has over gas chromatography (GC) is that SFC can efficiently separate thermally labile compounds. The disadvantage of SFC is that the polarity of the mobile phase is limited. Highly polar solutes are not soluble in supercritical fluids, even when modifiers are added. SFC is commonly used to separate petroleum distillates and by-products, moderately polar pesticides and herbicides, and more recently for the separation of chiral compounds, such as pharmaceutical drugs.

1 INTRODUCTION

SFC employs fluids at temperatures and pressures above their critical temperatures ($T_c$) and critical pressures ($P_c$). When used as chromatographic mobile phases, supercritical fluids are able to solvate moderately polar analytes that are difficult to volatize in GC, but are still compatible with GC detectors. Whenever analytes could be separated by either LC or by SFC, the latter provides higher efficiency, shorter analysis time, lower pressure drop across the column and wider choices of detectors. Of the numerous supercritical fluids studied, carbon dioxide has found the widest application in SFC due to a number of advantages, including mild critical parameters, inertness, environmental friendliness, low cost and easy access to high purity. With solvating power equivalent to that of pentane or hexane under supercritical conditions, pure carbon dioxide cannot solvate and elute high polarity analytes very easily. Recent developments in the applications of polar modifiers to the carbon dioxide mobile phase in packed column supercritical fluid chromatography (pSFC) have established the place of SFC in modern chromatographic sciences. Other high fluidity mobile phases are also under study (1–3). These include subcritical, near-critical, enhanced-fluidity liquids and solvating gases.

In this chapter, the fundamental merits of using supercritical fluids and other high fluidity mobile phases in chromatography, the relationship of SFC to GC and high-performance liquid chromatography (HPLC), instrumentation of SFC and common mobile and stationary phases are discussed.
LIQUID CHROMATOGRAPHY

THEORY AND PRINCIPLES OF SUPERCRITICAL FLUID CHROMATOGRAPHY

2.1 Properties of Supercritical Fluids

A supercritical fluid corresponds to a condition where the compound is compressed above its critical pressure \( (P_c) \) and heated above its critical temperature \( (T_c) \) (Figure 1). Supercritical fluids have properties that are similar to those of both gases and liquids. The density of a supercritical fluid is close to that of a liquid, while its viscosity approaches that of a gas, and diffusion coefficients of supercritical fluids are typically intermediate between those of gases and liquids (Table 1). The phase change between gas and liquid is accompanied by abrupt physical property changes. However, the transition to and from the supercritical state is continuous and no abrupt changes in physical properties occur when passing through the critical point.

Figure 2 shows the approximate regions occupied by mobile phases used in GC, SFC and LC on a diffusion coefficient, \( D_m \), vs density, \( \rho \), plot. Also, Figure 2 clearly shows the large difference in diffusion coefficients between gases and liquids.

Because supercritical fluids are highly compressible, the properties of supercritical fluids vary with pressure. For example, the density of supercritical \( \text{CO}_2 \) at approximately \( 40°C \) can be varied from 0.25 to 0.8 \( \text{g cm}^{-3} \) by changing the pressure from 75 to 300 bar. Accordingly, the solvent strength of a supercritical fluid can be varied by changing the pressure, which also means that analyte solubility is controlled by pressure variation. Similarly, mass transport properties, such as viscosity and diffusion rates, vary with pressure. The precise control of solvent properties by fine tuning the pressure of supercritical solvents is unsurpassed by any other phase.

Carbon dioxide, \( \text{CO}_2 \), is the most commonly used supercritical fluid. Its low critical temperature and pressure (31.3°C and 72.8 atm) allow most separations to be undertaken near room temperature. \( \text{CO}_2 \) also has low toxicity and is environmentally benign. \( \text{CO}_2 \) is also highly compatible with a large range of detectors. However, the solvent strength of \( \text{CO}_2 \) is low. Even under high pressures, polar analytes will not dissolve in supercritical \( \text{CO}_2 \).

The solvent strengths of supercritical fluids were experimentally measured by monitoring the shift of the ultraviolet/visible (UV/VIS) absorbance maxima for a number of solvatochromic dyes. The solvent strength of \( \text{CO}_2 \) was shown to be close to that of pentane.
or hexane. Despite the low polarity of supercritical CO2, it remains the dominant mobile phase for SFC in applications to date due to the merits referred in the previous section. Furthermore, polarity enhancement of CO2-based mobile phases is accomplished by the addition of polar modifiers and/or additives.

2.2 Why Supercritical Fluid Chromatography?

The major chromatographic advantages of using supercritical fluids are lower viscosity and higher diffusivities and concomitant higher efficiency, increased speed of analysis and lower pressure drop, as compared to LC. The connection between fast mass transport properties and improved chromatographic performance is delineated in the following sections.

2.2.1 Band Dispersion as a Function of Mobile Phase Velocity

The van Deemter equation will be used to correlate chromatographic efficiency with the mobile phase velocity. An uncoupled van Deemter equation\(^\text{(1)}\) for packed columns in LC is given by Equation (1):

\[
H = A + \frac{B}{u} + Cu
\]

where \(H\) is the plate height (or band dispersion), \(u\) is the linear velocity of the mobile phase, and \(A\), \(B\) and \(C\) are velocity-independent parameters that are determined by the properties of the mobile and stationary phases. The \(A\) term is the contribution from multiple flow paths of a packed column, the \(B\) term is the contribution to band dispersion from longitudinal (along the flow axis) diffusion and the \(C\) term represents the combined obstruction of mass transfer in the mobile phase and the stationary phase or \(C_m\) and \(C_s\). The \(B\) and \(C\) terms can be further expressed by Equations (2) and (3):

\[
B = \gamma D_m
\]

\[
C = \frac{f(k')}{D_m}
\]

where \(\gamma\) is the obstruction factor, \(k'\) is the retention factor and \(D_m\) is the average diffusion coefficient of the solute in the column. For incompressible mobile phases, \(D_m\) is independent of pressure, while for compressible mobile phases, such as in GC and SFC, \(D_m\) is influenced by flow rate when column pressure is a function of flow rate. More complicated expressions have been used to approximate the relationship between the average column pressure and the flow rate for compressible mobile phases.\(^\text{(12)}\) Nevertheless the results from the more complicated model were comparable to the conclusions shown below.

For the sake of simplicity, the independence of \(D_m\) on the column flow rate is assumed.

By taking the first derivative of Equation (1) with respect to \(u\) and setting the derivative to zero, the optimal mobile phase velocity, \(u_{\text{opt}}\), for the minimum plate height, \(H_{\text{min}}\), is obtained, as shown in Equations (4) and (5):

\[
u_{\text{opt}} = D_m\sqrt{\frac{\gamma}{f(k')}}
\]

and

\[
H_{\text{min}} = A + \sqrt{2\gamma \times f(k')}
\]

Equation (4) shows that \(u_{\text{opt}}\) is proportional to \(D_m\); thus, the mobile phase with higher solute diffusivity gives higher \(u_{\text{opt}}\). Since the diffusion coefficient of a solute in a supercritical fluid is larger than that in liquids, the \(u_{\text{opt}}\) using supercritical mobile phases is higher than using a liquid solvent. At high velocities the plate height is dominated by the \(C\) term, and is inversely proportional to \(D_m\). Higher \(D_m\) values result in a small \(C\) term, which means smaller band dispersion and higher efficiency in the high velocity range. Equation (5) indicates that \(H_{\text{min}}\) (or maximum efficiency) is independent of \(D_m\) or the mobile phase properties. In other words, the maximum efficiency using a particular column is irrelevant to the type of chromatography, i.e. in principle GC, SFC and LC generate the same efficiency at their individual optimal flow rates. However, practically, the optimal linear velocity, \(u_{\text{opt}}\), for LC using a typical column is small. Thus, the routine practice of HPLC is at much higher linear velocity than its optimum value, which results in lowered efficiency. At a high mobile phase velocity, the efficiency decreases in the order of GC, SFC and LC. In summary, for samples previously only amenable to HPLC, SFC provides higher efficiency and shorter analysis time, while for samples just beyond the scope of GC, SFC analysis is not compromised severely on efficiency and analysis time.

2.2.2 Effect of Viscosity on Chromatographic Performance

Equation (6) shows the relationship between the pressure drop and the mobile phase viscosity as described by Darcy’s law:\(^\text{(13)}\)

\[
\Delta P = \frac{\phi \eta u L}{d_p^2}
\]

where \(\phi\) is a dimensionless flow resistance parameter, \(\eta\) is the viscosity of the mobile phase, \(u\) is the average linear velocity, and \(L\) and \(d_p\) are the column length and the particle diameter. Darcy’s law indicates that a lower pressure drop across the column can be obtained by decreasing
the viscosity of the mobile phase. Therefore, for the same column and flow rate, SFC has a lower pressure drop than LC. The lower pressure drop across a column in SFC allows longer columns or more columns to be coupled together to obtain higher efficiency and better separation.

### 2.3 Closely Related Chromatographic Techniques and Unified Chromatography

The properties of a fluid, i.e., density, viscosity, diffusion coefficient and solvating power, change continuously near the critical point. Therefore, chromatographic systems using other portions of the phase diagram that are near the critical point may have merit as well. Subcritical fluid chromatography (chromatography done under liquid state conditions that are near the critical point) often has similar objectives and uses the same instrumentation as SFC. Sometimes, subcritical fluids are preferred to supercritical fluids when the critical temperatures of the mobile phases are too high, or the analytes are thermally labile. For example, because chiral separations are often enthalpy controlled, the selectivity of the separation is improved by decreasing the temperature of the separation (i.e., using subcritical conditions).

Other approaches have also been taken to generate mobile phases with low viscosities and high diffusivities. These include high-temperature liquid chromatography (HTLC) and enhanced-fluidity liquid chromatography (EFLC). In high temperature HPLC the column temperature is raised to lower the mobile phase viscosity. For example, at 60 °C the viscosity of water is about half of that at 20 °C, HTLC using heated water (up to 210 °C and 20 bar) and acetonitrile (up to 150 °C) has been reported. The lower viscosity at high temperatures is accompanied by higher vapor pressure and the column outlet pressure was increased above atmospheric pressure to prevent the mobile phase from boiling. Enhanced-fluidity HPLC involves the addition of a low-viscosity liquid, such as liquid CO₂ or liquid fluoroform, to organic solvents. This greatly lowers the viscosity of the solvent while maintaining a solvent strength similar to that of the pure organic solvent.

While SFC fits between GC and LC, HTLC and EFLC are techniques that provide a continuum between SFC and LC, and solvating gas chromatography (SGC) is an effort to bridge the gap between GC and SFC. In SGC, where capillary SFC instrumentation is commonly used, high pressures are exerted at the column inlet to maintain a supercritical, subcritical or liquid state of the mobile phase, but low pressures (slightly higher than atmospheric) at the column outlet result in phase transitions down the length of the column. Examples of SGC include the use of carbon dioxide and ammonia as mobile phases.

In all these studies, a common and key point is to maintain the column outlet pressure at a pressure greater than atmospheric pressure. Once the outlet pressure is controlled, gases can be compressed to supercritical fluid conditions or liquid state conditions. In fact, the mobile phase can essentially span between liquid and gas phases depending on the application without the necessity to distinguish the exact state in practice. This prompted the concept of “unified chromatography”.

### 2.4 Capillary Supercritical Fluid Chromatography Versus Packed Column Supercritical Fluid Chromatography

Capillary supercritical fluid chromatography (cSFC) experienced rapid development in the 1980s, while pSFC did not rival and prevail over cSFC until the early 1990s. Although packed capillary columns are also used, cSFC will be used in this text to refer to open tubular capillary column SFC.

cSFC and pSFC differ in instrumentation and application. The column pressure of cSFC is usually maintained through the upstream pump and the after-column fixed restrictor. Higher flow rates are associated with higher column pressures. Owing to the low ratio between the stationary phase volume to column void volume, cSFC has a lower pressure drop per unit column length, which allows long column lengths to be used to achieve high efficiency. cSFC has high peak capacity and is well suited to analyze complex mixtures. In cSFC a single pump is used to deliver a neat mobile phase and pressure programming is common. Direct coupling of GC detectors, such as flame ionization detectors (FIDs), is advantageous for high sensitivity measurements. However, insufficient solvating power of the mobile phase (CO₂ normally) even at high pressures precludes it from analyzing moderately or highly polar compounds.

pSFC is primarily used for analysis of polar analytes that are beyond the scope of cSFC through the use of polar modifiers. It has a larger ratio of the stationary phase volume to column void volume, leading to higher retention and necessitating the use of stronger eluent, such as polar modifiers. Compared with cSFC, pSFC has a higher flow rate and consequently a high pressure drop. The pressure gradient along the column results in gradients of mobile phase density, diffusion coefficient of the solute and flow rate along the column. Although pressure drops can be greater than 100 atm, no serious compromise on column efficiency is observed. pSFC gives shorter analysis time and higher efficiency per unit time. The large mass flow permits the usage of a double pump system for preparing binary or ternary mobile phases. It also makes independent control of flow rate and
pressure possible, which is critical in decoupling the two for method development and optimization. The column pressure is controlled by a (electronically controlled) pressure regulator placed after the column. Polar modifier and/or additive, supplied from the second pump, are normally used to enhance the eluting power and solubility of analytes. pSFC uses LC columns, which provides a wide stationary phase selection. Inherently, pSFC exhibits higher sensitivity, reproducibility and sample loadability. However, pSFC cannot use some GC detectors, such as FIDs, due to the presence of the modifier. Recent advances in technology have made modern packed column supercritical fluid chromatographs commercially available, which has greatly promoted the development and popularity of pSFC.

3 INSTRUMENTATION

The main components of the SFC chromatograph include pump, injector, oven, column, pressure control device and detector. The instrumentation used for cSFC and pSFC is not the same. Schematic block diagrams for chromatographs used in pSFC and cSFC are shown in Figure 3.

3.1 Pump and Mixer

The chromatograph for cSFC usually contains a single syringe pump for delivering neat or premixed mobile phase, while that for pSFC often contains a high pressure reciprocating pump and an additional microflow high pressure pump for delivering the modifier and additive. The syringe pump in cSFC typically delivers mobile phase fluid at a rate of 1 to 80 $\mu$L min$^{-1}$, whereas, the reciprocating pump in pSFC works in a range of 0.5 to 10 mL min$^{-1}$ and the microflow pump delivers modifiers in the range of 1–20% of the fluid.$^{33-36}$ The mobile phase, e.g. CO$_2$, is normally from pressurized cylinders. For precise delivery of the fluid, compressibility compensation has to be included in the pumping process. For pSFC, owing to the large flow rate, a reciprocating pump is required for uninterrupted delivery of the mobile phase. Precise control of temperature at the pump head is essential for compressibility compensation.$^{37}$ Because the compressing process is exothermic, the pump head is usually well chilled using a circulating bath or thermoelectric (Peltier) cooler.

For pSFC, the pressurized fluid and modifier are dynamically mixed at the high pressure mixer. A pulse damper is usually placed in line to smooth the fluid pulsation produced by reciprocating pumps.

Figure 3 Schematic diagrams showing the instrumental set-up for (a) pSFC and (b) cSFC. In pSFC, two pumps and an online mixer are normally used to deliver a mixture of mobile phases. The column outlet pressure is maintained by the back pressure regulator. To use GC detectors, flow splitting before the back pressure regulator is necessary. In cSFC, a single pump is normally used to deliver pure or premixed mobile phase. The column pressure is controlled at the inlet by the pump, resulting in the coupling of column pressure and flow rate.
3.2 Sample Injection

The amount of sample that can be introduced depends on the type of SFC. In cSFC, the injection volume is about 0.5 nL. To obtain reproducible injections for such a small volume, an injection valve with a split mechanism is necessary. Currently, two designs are commonly used, the split/splitless \(^{33,38} \) and the timed-split \( ^{36,39} \) Both allow injection of only a fraction of the sample loaded in the internal loop.

In pSFC a standard LC rotary injector with loop size of 5 to 20 \( \mu \)L can be used. When a large loop size is used, special precautions should be taken when switching the valve from injection position to loading position to minimize band dispersion because the expansion of the high-pressure fluid is vigorous. Since SFC is usually normal-phase chromatography (see discussion later), an injection solvent of weaker polarity than the mobile phase is preferred in order to minimize interference of the injection solvent with the analyte retention. When injection solvents are used that are too strong, analytes tend to flow down the column with the solvent plug for a significant fraction of the column length instead of interacting with the stationary phase. This leads to peak widening and poor selectivity. Thus, when polar solvents (e.g. water or methanol) cannot be avoided, the injection volume should be minimized. When large volumes of diluted solute are to be used, preconcentration or adsorption of the solute onto a precolumn or guard column mounted at the loop position is useful.

3.3 Column and Oven

The column temperature of cSFC is maintained using GC-type ovens. pSFC uses LC-type ovens. An upper temperature limit of 200 °C is normally sufficient. In fact, a significant proportion of the published pSFC experiments are run at subcritical conditions. Furthermore, the capability of the pSFC oven to lower temperature to subzero ranges is beneficial for enhancing selectivity of the separation, particularly for chiral separations.\(^{40,41}\)

The columns for SFC are typically made of fused silica with diameter of 0.025 to 0.1 mm and length of 1 to 35 m. The stationary phases are discussed in detail in a later section. The columns for pSFC (including microbore columns) are the same as those used in LC with dimensions of 0.5 to 4.6 mm inner diameter, 3 to 25 cm long and are normally made of stainless steel. Typical pSFC columns are packed with totally porous silica particles 3 to 10 \( \mu \)m in size.

3.4 Pressure Control

The mobile phase flow rate in cSFC is maintained typically by placing a small diameter open tube at the end of the column.\(^{42}\) The pressure of the cSFC system is controlled by the outlet pressure of the pump. A pressure gradient, frequently used in cSFC, is generated by a programmed flow rate gradient. However, decreased column efficiency will result if the flow rates become too high. Independent pressure control and flow rate control in cSFC by using a pressure regulator with very small dead volume to accommodate the mass flow is still too technically challenging. However, precise independent pressure control is possible and has been implemented in pSFC by placing a pressure regulator after the column. An electromagnetically controlled needle or piston inside the regulator controls the closing and opening of an orifice in conjunction with the flow rate to maintain a specified pressure.

3.5 Detection

Generally speaking, SFC is superior to HPLC in the range of compatible detection methods, because most detectors used in GC can also be used in SFC, particularly for \( \text{CO}_2 \)-based mobile phases. The applicability of a specific detector, though, depends on the nature of the analyte, flow rate and composition of the mobile phase.

The compatibility of SFC with the FID is one of its strengths. As a universal detection method with high sensitivity and wide dynamic range (~10^5), FID is the detector of choice in cSFC, when normally no organic modifier is used and flow rate after mobile phase expansion is compatible with FID. However, for pSFC, GC detectors usually cannot be used directly due to the large mass flow and the use of combustible organic modifiers. To lower the mass flow, a flow splitter through a restrictor at a “zero-dead volume” tee is generally employed,\(^{(1)}\) which does not interfere with the back pressure regulators. Two polar modifiers that do not produce FID response are water and formic acid. Use of subcritical water as mobile phase at 80 to 175 °C in the analysis of small alcohol compounds, hydroxyphenols and amino acids with flame ionization detection was reported by Miller and Hawthorne.\(^{(17)}\) Other low-pressure detectors commonly used in SFC include the thermionic ionization detector (TID),\(^{(43,44)}\) the flame photometric detector (FPD),\(^{(45,46)}\) the nitrogen–phosphorus detector (NPD),\(^{(47,48)}\) the electron-capture detector (ECD),\(^{(18,49,50)}\) and the chemiluminescence detector.\(^{(51,52)}\)

An alternative universal detector to the FID, which is compatible with mobile phase modifiers, is the evaporative light-scattering detector (ELSD).\(^{(53)}\) It is less sensitive and has a narrow dynamic range (~10^3). Encouraging results using ELSD in SFC have been reported.\(^{(54,55)}\)

UV absorption detectors are the most commonly used detection method in pSFC for analytes with UV-chromophores. However, differing from HPLC, the flow
cell must be capable of withstanding pressures up to 400 bar, because it is placed in-line before the pressure regulator. Other high pressure detection methods that are commonly used in SFC include fluorescence detection. Owing to the high column temperature usually used in SFC, to prevent interference of the UV or fluorescence detection from refractive index fluctuations during the cooling process, a heat exchanger placed before the detector is often used.\(^1\)

Mass spectrometry (MS) affords a highly sensitive and selective means of detection. Numerous methods of coupling SFC to MS have been published.\(^{1,56-61}\) Thermospray, electro spray, particle beam and atmospheric pressure chemical ionization (APCI) have attracted the most attention.\(^{51}\) Atmospheric pressure ionization (electrospray and APCI) is currently undergoing the fastest growth, because it allows independent optimization of SFC and MS.\(^{51}\)

Other detection methods that are increasingly used in SFC include Fourier transform infrared (FTIR) spectroscopy,\(^{62,63}\) nuclear magnetic resonance (NMR),\(^{64,65}\) and electrochemical\(^{66}\) and amperometric detectors.\(^{67,68}\)

### 4 STATIONARY PHASES FOR SUPERCRITICAL FLUID CHROMATOGRAPHY

The stationary phases for cSFC and pSFC are different. The stationary phases in cSFC are often those also used in GC, but they are typically further crosslinked when used for SFC. The film thickness of the stationary phase is typically 0.1 to 3 \(\mu\)m. The most commonly used stationary phases are polysiloxanes.\(^{69}\) The polarity of the stationary phase is varied by using polysiloxanes with different substituent groups, among which methyl, phenyl and cyano are common choices. Combinations of these groups in different ratios satisfy various polarity needs. For example, dimethylpolysiloxane (100% methyl), phenylmethylpolysiloxane (50% phenyl, 50% methyl), cyanopolysiloxane (100% cyano) and cyanopropylmethylphenylmethylsiloxane are common stationary phases used in cSFC.

The stationary phases for pSFC are similar to those in HPLC. Porous silica is the most common particle for pSFC. The silica packing consists of silica particles (3–10 \(\mu\)m diameter) with 50–500 \(\AA\) pore sizes and 50–500 \(\text{m}^2\text{g}^{-1}\) surface area. The polarity of the porous silica is often modified through the attachment of a variety of groups to the organosilane groups. Common functional groups include methyl, phenyl, diphenyl, naphthyl, octadecyl, octyl, diol, cyanopropyl and aminopropyl groups. Unreacted silanol groups are deactivated by end-capping with silylation reagents (e.g. trimethylmethoxysilane). However, residual silanol groups always exist. Active sites on the surface of the particle interact strongly with polar analytes when neat \(\text{CO}_2\) is used as the mobile phase, causing poor peak shapes in the chromatogram.\(^{70-73}\) The addition of polar modifiers into the mobile phase effectively improves the chromatographic band shape as well as lowers the retention of the analyte.\(^{74}\) Mobile phase modifiers are discussed in detail in the next section. Coating the silica particles with a thin layer of organic polymer is another approach to produce a stationary phase for SFC. Polymer coated silica stationary phases showed improved peak shapes, but still a polar modifier is necessary for effective elution of polar analytes.\(^{1}\) Totally polymer-based particles, such as those made from polystyrene–divinylbenzene are also used. However, peak tailing is very common with polymeric surfaces as well. In addition, polymer-based particles often swell when exposed to supercritical mobile phases and exhibit less temperature and pressure (mechanical) resistance.\(^{1}\)

For most of the stationary phases used in pSFC, the apparent mechanism of separation is normal-phase chromatography.\(^{1}\) For HTLC and EFLC, where \(\text{CO}_2\) is not the primary mobile phase, other modes of chromatography, such as reversed-phase, can be easily implemented.

### 5 MOBILE PHASES FOR SUPERCRITICAL FLUID CHROMATOGRAPHY

#### 5.1 Pure Fluids

Pure fluid mobile phases provide simplicity of operation and often better detector compatibility. Therefore, whenever possible, pure fluids should be considered first. Pure \(\text{CO}_2\) is the common first choice. It has been used in the analysis of nonpolar and moderately polar analytes. \(\text{CO}_2\) has no permanent dipole moment but has a relatively large quadrupole moment allowing some interactions with polar analytes.\(^ {75}\) \(\text{CO}_2\) is suitable for cSFC where a pressure gradient is commonly used to change the retention of solutes. Unlike GC, a temperature gradient is generally not applicable, since under similar pressure, increasing temperature decreases the density and solvent strength of the mobile phase, and therefore increases retention. However, the solvating power of \(\text{CO}_2\) is quite limited even under high pressures.

Other pure solvents are also used in SFC. Low-molecular-weight alkanes,\(^ {76-78}\) such as ethane, propane, pentane and hexane, have been used. They exhibit stronger solvent strength than \(\text{CO}_2\) and provide different selectivity toward compounds such as polycyclic aromatic hydrocarbons.\(^ {71}\) Their flammability and incompatibility
with FID greatly reduce their popularity. Nitrous oxide has the polarity and critical parameters similar to those of CO₂. It was used in SFC in the early stages of the technique, but no particular advantage was found,\(^{71}\) while its explosive propensity when used for samples with high organic content\(^{79}\) deterred further applications.\(^{80}\) Sulfur hexafluoride is primarily used in the analysis of hydrocarbons.\(^{81}\) Its compatibility with FID is not as good as carbon dioxide, but it has a wider transparent window for infrared (IR) detection. Trifluoromethane (fluoroform) has a permanent dipole moment and has a lower \(T_c\) (26.2 °C) and \(P_c\) (48.0 atm) than CO₂.\(^{82}\) It is also not involved in ozone destruction.\(^{83}\) It exhibits greater selectivity in the SFC analysis of polycyclic aromatic hydrocarbons than CO₂, nitrous oxide, ethane and CClF\(_3\)\(^{73}\) and has stronger eluotropic power than CO₂ and methanol-modified CO₂.\(^{84}\) The use of other hydrofluorocarbons in SFC is also under study.\(^{85}\)

The choices for pure polar solvents for SFC are quite limited. Water, despite its unmatched low cost and environmental friendliness, has high critical parameters (374.1 °C and 217.6 atm). Chromatography using subcritical water has been reported.\(^{18}\) Ammonia, a highly polar solvent with critical temperature and pressure of 132.4 °C and 112.0 atm, has been used as the chromatographic mobile phase in quite a few studies under supercritical or subcritical conditions\(^{4,86,87}\) as well as for SGC.\(^{24}\) However, the corrosive and toxic nature prevents it from being widely investigated.

Other than CO₂, none of the pure solvents examined are likely to find wide use. Their applications are preferred only when markedly better selectivity occurs or when CO₂ fails (e.g. because of reactivity toward the sample). Within the foreseeable future, CO₂ and CO₂ with polar modifiers will still dominate the SFC studies.

**5.2 Binary or Ternary Mobile Phases**

The addition of low percentages (e.g. 1–20%) of polar modifiers into CO₂ is an efficient means to enhance the solvent strength of mobile phase. However, the use of modifiers compromises the compatibility with most GC detectors. For instance, even a small amount of a combustible modifier (e.g. methanol) generates background signal in the FID. Only water and formic acid are exceptions.

The solvent strength enhancement of polar modifiers is disproportionate to its composition in the mixture. For example, the addition of 5% methanol to CO₂ increases the solvent strength to slightly greater than 25% of that of pure methanol.\(^{88}\) To further improve the solvent strength of the mobile phase or the peak shape of the analyte, a third highly polar component is sometimes added at low concentrations (generally 0.1–1%). For example bases, water, and acids have been added to the modifier to improve performance.

The effects of adding polar modifiers or additives are multifaceted. The modifier can increase the solubility of the analyte, enhance the eluting power of the mobile phase and improve the chromatographic peak shape of the analyte. The solubility enhancement generally follows the solvent strength of the modifier, whereas, other effects depend on the interactions between the mobile phase–solute, mobile phase–stationary phase and solute–stationary phase pairs.\(^{89}\) For example, the addition of methanol to CO₂ did not improve the elution of chrysene from an octadecylsilyl column, while the same methanol–CO₂ mixtures dramatically decreased the retention factor of chrysene on a sulfonic acid column.\(^{1}\) The ability of modifiers to improve poor peak shapes is caused by the blocking of “active sites”\(^{90,91}\) (residual silanol groups on silica which provide secondary retention mechanisms) on the stationary phase. Other potentially useful interactions between the modifier and the solute include ion-pairing with the analyte\(^{92}\) and suppression of analyte ionization.\(^{93,94}\) The mechanism by which the modifier and solute interact is still a controversial issue. As a general rule, additives with similar functionality to the solute are most effective in improving the elution profile.\(^{75}\)

The addition of modifiers or additives also increases the critical parameters (\(T_c\) and \(P_c\)) of the resultant mixtures. The degree of change depends on the critical parameters of the modifier or additive and the proportion of modifier added. Methanol–CO₂ mixtures, the most frequently employed system, show moderate increases in \(T_c\) and \(P_c\), e.g. CO₂ with 20% methanol exhibits \(T_c\) and \(P_c\) of 72.2 °C and 76.7 atm, respectively.\(^{95}\) When binary and ternary mobile phases are used, the chromatographic separation is often actually at subcritical mobile phase conditions.

The phase behavior of the binary or tertiary mobile phase must be known to avoid phase separation in the column and therefore to achieve high efficiency separations. Phase diagrams for commonly used mixtures of mobile phases are available, e.g. methanol–CO₂,\(^{96,97}\) methanol–CHF₃,\(^{98}\) methanol–water–CO₂,\(^{92,93}\) and methanol–water–CHF₃,\(^{94}\) and tetrahydrofuran–CO₂.\(^{99}\)

Binary and ternary mixtures for SFC can be prepared as premixed or through online mixing. The premixing of solvents provides accurate control of the composition and requires simple chromatographic design. Premixed CO₂ and methanol mixtures or other commonly used modifiers are commercially available in cylinders. However, due to the difference in the vapor pressure of the components, compositional change can occur with usage. For example, a more than twofold change in retention time was reported using premixed methanol–CO₂ throughout the
usage of the cylinder, due to presumably an increase in methanol concentration in the cylinder with time.\(^\text{100}\) Online mixing requires two high pressure pumps and accurate control of the delivery ratio from the pumps, but it allows a quick change in modifier concentration and use of a modifier gradient.

Enhanced-fluidity liquids are low viscosity fluids that target the insufficient solvating power of supercritical CO\(_2\) in chromatography and extraction. Instead of adding a polar modifier to CO\(_2\), EFLC adds liquid CO\(_2\) or other low viscosity liquids to common organic solvents.\(^{21,22,101,102}\) The column pressure is maintained at a value high enough to ensure that the liquid is a single-phase system. The fluidity enhancement observed from the addition of liquid CO\(_2\) to common liquids is significant. For example, by adding 40\% CO\(_2\) to methanol the viscosity decreased by approximately 50\% while the solvent strength remains similar to that of pure methanol. While most CO\(_2\)-based SFC is restricted in normal-phase chromatography, EFLC has been applied to normal,\(^{103}\) reversed-phase,\(^{22,97}\) and size-exclusion\(^{95,104}\) chromatographies. In fact, EFLC can be viewed as bridging the gap between SFC and HPLC.

6 PERSPECTIVES AND FUTURE DEVELOPMENT

Although SFC was first demonstrated in 1960,\(^{105}\) its major development and recognition of its importance occurred during the early 1990s. Currently, SFC is a standard analytical method alongside GC and LC in many laboratories. It tends to replace normal-phase LC. SFC has found diverse applications in all types of chromatographic analysis traditionally accomplished by GC and HPLC. Numerous reviews and monographs are available on the applications of SFC.\(^{1,2,30,75,106}\) SFC has been used for the analysis of common chemicals, petroleum-based compounds, pharmaceuticals, food components, natural products, biologically active compounds, agricultural chemicals, synthetic polymers and environmental contaminants.

In the coming years, further applications of analytical and preparative-scale SFC for the separation of chiral pharmaceuticals are expected. Compared to chiral GC, SFC not only extends the sample applicability but also allows separations at lower temperature to prevent potential racemization. For chiral samples amenable to HPLC analysis, SFC provides higher efficiency, a critical parameter in increasing enantiomeric resolution, and shorter analysis time. Enantiomeric separation at cryogenic temperatures using SFC potentiates higher enantiomeric selectivity at much faster speeds compared to HPLC. SFC is also advantageous in preparative chiral separation and solvent removal.

Studies of the mechanism of modifier or additive continue. As the idea of “unified chromatography” prevails, more investigations are expected in emerging areas, such as SGC, EFLC and HTLC.

Thin-layer Chromatography

Joseph Sherma
Lafayette College, Easton, USA

1 Introduction

TLC is a type of liquid chromatography in which the stationary phase takes the form of a layer on a glass, aluminum, or plastic support. The term “planar chromatography” is often used for both TLC and paper chromatography (PC) because each employs a planar stationary phase rather than a column. PC, which utilizes plain, modified, or impregnated paper (cellulose) as the stationary phase, involves many of the same basic techniques as TLC, but it has not evolved into an efficient, sensitive, quantitative, instrument-based analytical method and has many disadvantages relative to TLC. PC will not be covered in this article.

Originally developed in 1951 by J.G. Kirchner and colleagues, later standardized by E. Stahl and colleagues, and still widely practiced today, classical, capillary-action TLC is an inexpensive, simple method requiring little instrumentation, which is used for separation of simple mixtures and for qualitative identification or semiquantitative, visual analysis of samples. By contrast, modern TLC (usually termed high-performance thin-layer chromatography, HPTLC), which began around 1975 with the introduction by Merck of high-efficiency, commercially precoated plates, is an instrumental technique carried out on efficient, fine-particle layers. HPTLC is capable of producing fast, high-resolution separations and quantitative results with accuracy and precision rivaling those of...
LIQUID CHROMATOGRAPHY

2 SAMPLE PREPARATION

Sample preparation procedures for TLC are similar to those for GC and HPLC. In order for the solution to be spotted, it must be sufficiently concentrated that the analyte can be detected in the applied volume, and pure enough so that it can be separated as a discrete, compact spot or zone. The solvent in which the sample is dissolved must be suitable in terms of viscosity, volatility, and ability...
to wet the layer, and not have the potential for unintended predevelopment during sample application.

Relatively pure samples or their concentrated extracts can often be directly spotted for TLC analysis. If the analyte is present in low concentration in a complex sample, solvent extraction, clean-up (purification), and concentration procedures must precede TLC. Because layers are not reused, it is often possible to apply cruder samples than could be injected into a GC or HPLC column, including samples with irreversibly sorbed impurities. However, impurities that co-migrate with the analyte, adversely affect its detection, or distort its zone (i.e. cause streaking or trailing) must be removed prior to TLC. Carryover of material from one sample to another is not a problem as it is in on-line column methods involving sequential injections, so sample preparation is often simpler for TLC than for these other chromatographic methods.

Common clean-up procedures include liquid–liquid extraction, column chromatography, desalting, and deproteinization. Solid-phase extraction (SPE) using small, disposable columns or membrane disks has recently become widely used for isolation and clean-up of samples prior to TLC analysis. Supercritical fluid extraction (SFE) has been directly coupled to TLC for analysis of solid samples or solutions loaded on glass fiber filters. A derivative of the analyte can be formed in solution prior to spotting, or in situ at the origin by overspotting of a reagent, in order to improve resolution or detection. Special plates with preadsorbent zones serve for sample clean-up by retaining some interfering substances.

3 STATIONARY PHASES

TLC and HPTLC plates are commercially available in the form of precoated layers supported on glass, plastic sheets, or aluminum foil. HPTLC plates are smaller (10 × 10 cm or 10 × 20 cm), have a thinner (0.1–0.2 mm) more uniform layer composed of smaller-diameter particles (5–6 μm), and are developed over shorter distances (3–7 cm) compared with classical 20 × 20 cm TLC plates, which have a 0.25-mm-thick layer of 12–20 μm particle size and are developed for 10–12 cm. Optimal development distances are the point beyond which increased resolution of zones is offset by diffusion effects. Compared with TLC, HPTLC provides better separation efficiency and lower detection limits.

The choice of the layer and mobile phase is made in relation to the nature of the sample. Normal- or straight-phase adsorption TLC on silica gel with a less polar mobile phase, such as chloroform–methanol, is the most widely used mode. Lipophilic C-18, C-8, and C-2 bonded silica gel phases with a polar aqueous mobile phase, such as methanol–water, are used for reversed-phase TLC. Other precoated layers include alumina, magnesium silicate (Florisil), polyamide, cellulose, ion exchangers, and chemically bonded phenyl, amino, cyano, and diol layers. The last three bonded phases can function with multimodal mechanisms, depending on the composition of the mobile phase. Silica gel can be impregnated with various solvents, buffers, and selective reagents to improve separations. Chiral plates composed of a reversed-phase layer impregnated with copper acetate and a chiral selector, (2S,4R,2'S)-4-hydroxy-1-(2-hydroxydodecyl)proline, can be used to separate enantiomers through a ligand exchange mechanism. Preparative layers are thicker than analytical layers to provide higher sample capacity.

Layers are cleaned by predevelopment with or immersion in methanol prior to sample application, especially for quantitative and preparative applications. The most important manufacturers of TLC plates are Merck, Whatman, Analtech, and Macherey-Nagel, and literature from these companies should be consulted for details of availability, properties, usage, and applications.

4 MOBILE PHASES

Unlike GC, in which the mobile phase (carrier gas) is not a factor in the selectivity of the chromatographic system, the mobile phase in liquid chromatography, including TLC, exerts a decisive influence on the separation. In HPLC, the analyte passes through the on-line detector in the presence of the mobile phase, so solvents must be chosen not only to provide the required resolution but also to not absorb at the ultraviolet (UV) detection wavelength. In TLC the mobile phase is removed (evaporated) before the zones are detected, therefore a wider variety of solvents can be used to prepare mobile phases compared with HPLC.

The mobile phase is usually a mixture of two to five different solvents selected empirically using trial and error guided by prior personal experience and literature reports of similar separations. In addition, various systematic mobile phase optimization schemes involving solvent classification (selectivity) and the elutropic series (strength) patterned after HPLC have been described, most notably the PRISMA model based on Snyder’s solvent classification system as developed by Nyiredy. For normal phase (silica gel), the following 10 solvents from Snyder’s eight selectivity groups are used for exploratory TLC of the mixture: diethyl ether (group I), isopropanol and ethanol (II), tetrahydrofuran (III), acetic acid (IV), dichloromethane (V), ethyl acetate and dioxane (VI),
toluene (VII), and chloroform (VIII). Hexane (solvent strength = 0) is used to adjust the \( R_f \) values within the optimum range (0.2–0.8), if necessary. Between two and five solvents are then selected for construction of the PRISMA model that leads to identification of the optimized mobile phase. A similar procedure is followed for reversed-phase TLC (e.g. C\(_{18}\) bonded phase layer) using mixtures of methanol, acetonitrile, and/or tetrahydrofuran with water (solvent strength = 0).

TLC is usually carried out with a single mobile phase, rather than a mobile phase gradient which is often used in HPLC. Equilibration between the mobile phase and the layer occurs gradually during TLC development, and the mobile phase composition can change because different constituents migrate through the layer at different rates (solvent demixing). This leads to solvent gradients along the layer during “isocratic” TLC, the formation process of which is very different from the intentional, well-controlled gradients in a fully equilibrated HPLC column. Mobile phase selection for automated multiple development (AMD) will be described below in section 5.

5 APPLICATION OF SAMPLES AND STANDARDS

Application of small, precisely positioned initial zones from sample and standard solutions without damaging the layer surface is critical for achieving maximum resolution and reliable quantitative analysis. The volumes applied and the method of application depend on the type of analysis to be carried out (qualitative or quantitative), the layer (TLC or HPTLC), and the detection limit.

5.1 Sample Application as Spots

For TLC, 0.5- to 5-\( \mu \)L volumes are usually applied manually with a micropipet to produce initial zones with diameters in the 3–4 mm range. For HPTLC, initial zones in the form of spots with a maximum diameter of 1–2 mm are applied from a 100-nL to 1-\( \mu \)L fixed-volume, self-loading glass capillary pipet, which is held in a rocker-type mechanized spotting device (the Nanomat) that mechanically controls its positioning and brings the capillary tip into gentle and uniform contact with the layer to discharge the solution without damaging the layer. The volume precision of this applicator is below 1% (relative standard deviation, RSD). Variable volumes can be applied with a micrometer-controlled syringe.

5.2 Sample Application as Bands

Sample application in the form of bands is advantageous for high-resolution separations and precise (1% RSD) quantitative scanning densitometry using the aliquot technique (scanning with a slit of one-half to two-thirds the length of the applied band). Narrow, homogeneous sample bands of controlled length [1 mm (spot) to 190 mm] can be applied by use of a spray-on device (the Linomat) in which the plate is mechanically moved right to left in the \( x \)-direction beneath a fixed syringe from which 2–100 \( \mu \)L of sample (5–490 \( \mu \)L for preparative separations) is sprayed by an atomizer operating with a controlled nitrogen gas pressure. The bands are exactly positioned according to a coordinate system, which facilitates automated scanning after chromatogram development, or overspraying of samples with a reagent for in situ prechromatographic derivatization or with spiking solutions for validation of quantitative analysis by the standard-addition method. The ability to apply larger volumes to an HPTLC plate without loss of resolution lowers the determination limits with respect to the concentration of the solution, which aids in trace analysis. Complex, impure samples can often be successfully quantified, but only if bands are applied rather than spots.

In addition to band formation by instrumental means, sharp bands are also produced when samples are applied manually with a micropipet as diffuse vertical streaks to special plates containing a preadsorbent or concentrating zone. These plates, as well as the Linomat, facilitate quantitative analysis by allowing different volumes of the same standard solution to be applied to produce the densitometric calibration curve, rather than the same volume of a series of standards when spots are applied.

5.3 Automated Sample Application

Figure 2 shows the Automatic TLC Sampler III, which is a fully automated, computer-controlled device for sequential application of samples and standards from a rack of vials through a steel capillary as spots by contact transfer or as bands by a spray-on technique. The speed, volume, and pattern of standard and sample application are controllable, and a programmable rinse cycle can eliminate cross-contamination. Analyses performed with this applicator combined with densitometric chromatogram evaluation controlled by the same computer conform to good laboratory practice (GLP) and good manufacturing practice (GMP) standards.

6 CHROMATOGRAM DEVELOPMENT

Development times are typically in the range of 3–60 min, depending on the layer, mobile phase, and development method chosen. However, development time does not significantly influence the overall analysis time per
sample because many samples and standards can be chromatographed simultaneously.

6.1 Capillary Flow Thin-layer Chromatography

6.1.1 Ascending Development

The results of TLC are strongly dependent upon the environmental conditions during development, such as small changes in mobile phase composition, temperature, humidity, and the size and type of the chamber and its solvent vapor saturation conditions.

In the classical method of linear, ascending development TLC and HPTLC, the developing solvent is contained in a large-volume, covered glass tank (N-tank). The spotted plate is inclined against an inside wall of the tank with its lower edge immersed in the developing solvent below the starting line, and the solvent begins to rise immediately through the initial zones because of the capillary flow. As the mobile phase ascends, the layer interacts with the vapor phase in the tank. The space inside the tank is more or less equilibrated with solvent vapors, depending on the presence or absence of a mobile phase-soaked paper liner and the period of time the tank is allowed to stand before the plate is inserted. The use of a paper liner to provide saturation of the tank atmosphere with solvent vapors can be advantageous or detrimental, depending on the composition of the mobile phase.

More reproducible conditions can be established in an S-chamber (sandwich chamber), which consists of the TLC plate, a spacer of 3 mm thickness, and a cover- or counter-plate that is either blank glass or a solvent-soaked TLC plate. These parts are clamped together, so that the bottom 2 cm of the layer is uncovered, and are placed in a trough containing the mobile phase. Interaction between the layer, dry or wetted, and the gas phase is largely suppressed in an S-chamber, and reproducibility of the separation is improved.

The twin-trough chamber is an N-chamber modified with an inverted V-shaped ridge on the bottom dividing the tank into two sections, which allow development with only 4–20 mL of solvent, depending on the plate size, on one side, and easy pre-equilibration of the layer with vapors of the mobile phase or another conditioning liquid (e.g. a sulfuric acid–water mixture to control humidity) or volatile reagent on the other side.

A computer-controlled automatic developing chamber has been designed to provide reproducible isocratic one-dimensional (1-D) ascending development without operator attention. Parameters for preconditioning, N- or S-tank configuration, solvent migration distance, and drying with filtered cold or heated air are programmable via a key pad. The developing process is monitored, and elapsed time and running distance are continually displayed. Ten complete developing programs can be stored in computer memory.

6.1.2 Horizontal Development

The horizontal developing chamber permits simultaneous development from opposite edges to the middle of 60 sample spots on a 20 × 10 cm HPTLC plate, or 30 samples from one end to the other. The developing solvent, held in narrow troughs, is carried to the layer through capillary slits formed between the trough walls and glass slides. The chamber is covered with a glass plate during pre-equilibration and development and can be operated in N-type or S-type configurations, including humidity control by placing an appropriate sulfuric acid–water mixture in a conditioning tray. Use of the horizontal developing chamber allows separation conditions to be efficiently standardized, and only low amounts of mobile phase are required.

6.1.3 Continuous Development

The short bed continuous development (SB/CD) chamber is used for continuous development, which leads to
improved resolution of zones with low migration rates because of the larger effective separation distance. Four glass ridges and the back wall of the chamber support the plate at five different angles of inclination, each of which allows increasing lengths of the layer to protrude out of the top of the chamber. Solvent continually evaporates from the external layer at the top and is replaced by additional solvent drawn from the chamber at the bottom.

6.1.4 Gradient Elution Thin-layer Chromatography Combined with Automated Multiple Development

AMD generally involves 10–30 individual linear ascending developments of an HPTLC plate (usually silica gel) carried out in an AMD instrument, which includes an N-type chamber equipped with connections for feeding and releasing mobile phase and pumping a gas phase in and out, storage bottles for pure solvents and waste, a gradient mixer, syringes for measuring solvent volumes, and sensors for measuring migration distances. The developments are performed in the same direction with a stepwise mobile phase gradient that becomes progressively weaker (i.e. less polar) over distances that increase by 1–5 mm for each stage. The solvent is completely removed from the chamber and the layer is dried under vacuum applied by a pump for a preselected time after each development. The layer is then preconditioned with the vapor phase of the next batch of fresh solvent, which is fed into the chamber before the next incremental run.

The solvent strength may be changed for each development, or several stages may be carried out with the same solvent before changing its strength. The repeated movement of the solvent front through the chromatographic zones causes them to become compressed into narrow bands (width about 1 mm) during AMD, leading to peak capacities of more than 50 over a separation distance of 80 mm. Typical “universal gradients” for AMD are produced from methanol or acetonitrile (polar), dichloromethane, diisopropyl ether or tert-butylmethyl ether (medium polarity) and hexane (nonpolar). The central or basis solvent and the nonpolar solvent have the greatest effect on selectivity. By superimposing the densitogram of a chromatogram with a matched-scale diagram of the gradient, required modifications of the solvent system can be predicted.

Complex mixtures containing compounds with widely different polarities can be separated by AMD on one chromatogram, in which sharply focused zones migrate different distances according to their polarities. Zone widths are independent of migration distance and size of the starting zone, leading to high resolution and the ability to resolve relatively large samples for trace analysis. Migration distances of individual components are largely independent of the sample matrix, and detection limits are improved because of the highly concentrated zones that are produced.

Figure 3 illustrates a densitometer scan of a chromatogram produced by gradient AMD.

6.1.5 Two-dimensional Development

Two-dimensional (2-D) TLC involves spotting the sample in one corner of the layer, developing (ascending or horizontal) with the first mobile phase, drying the plate, and developing at a 90° angle with a second mobile phase having a diverse, complementary separation mechanism (selectivity). Computer simulation has been used to optimize 2-D separations based on 1-D data. Resolution (spot capacity) in 2-D TLC is greatly improved compared with 1-D TLC because sample components are resolved over the entire area of the layer, and is usually superior to that obtained by HPLC. Resolution by 2-D forced flow planar chromatography (FFPC) (see below) exceeds 2-D capillary flow TLC because spot diffusion is smaller. Disadvantages of 2-D TLC include a limit of one sample per plate and the time required for two developments and intermediate drying. In addition, quantitative calibration or qualitative identification standards cannot be developed in parallel on the same plate at the same time. Improved video densitometers may allow more reliable quantitative 2-D TLC in the future than is possible today with the commonly used slit-scanning densitometers.
6.2 Forced Flow Planar Chromatography

The mobile phase can migrate through the layer by capillary action, as is the case in the procedures described above, or under the influence of forced flow. FFPC has theoretical advantages relative to capillary flow, including independent optimization of mobile-phase velocity, higher efficiency, lower separation time, and use of solvents that do not wet the layer, but it requires specialized, complex commercial instrumentation. Forced flow is produced by mechanically pumping solvent through a sealed layer (overpressured layer chromatography, OPLC) or by spinning a glass rotor covered with sorbent around a central axis to drive the solvent from the center to the periphery of the layer by centrifugal force (rotation planar chromatography, RPC). Separations can be accomplished with a dry layer (off-line FFPC), but the closed system arrangement also allows the separation to be started after the layer is equilibrated with the mobile phase, similar to the situation in HPLC (on-line FFPC).

In RPC, samples are applied to the rotating stationary phase near the center, and centrifugal force plus capillary action drives the mobile phase through the sorbent from the center to the periphery of the plate. Up to 72 samples can be applied for analytical separations, and in situ quantification is possible. One circular sample is applied for micropreparative and preparative separations, which can be carried out off- and on-line. Various chambers are used for RPC, which differ mainly in the volume of the vapor space. The major commercial instruments for RPC are the Chromatotron 7924, CLC-5, and Rotachrom Model P. Although analytical applications have been proposed, RPC appears to be most useful for preparative applications.

OPLC combines many advantages of classical TLC and HPLC. Two commercial development chambers available for OPLC are the Chrompres 10 and Chrompres 25, which operate at pressures up to 10 and 25 atm respectively. The higher pressure of the Chrompres 25 allows the use of more viscous mobile phases and/or higher mobile phase velocities in the linear development mode. The chambers consist of a bottom support block and an upper block with a poly(methyl methacrylate) support plate, fixed in an external frame. The plate is placed on the surface of the bottom block, and the chamber is closed. A pump produces a water cushion against a flexible plastic membrane, which covers the layer and eliminates any vapor space, resulting in more reproducible separations under controlled conditions. A second pump forces mobile phase through the layer at a constant flow rate in the range of 1–12 mL min\(^{-1}\), leading to higher separation efficiency than is possible with capillary flow. A mobile-phase outlet is located in the upper block. To carry out linear chromatography, the layer must be specially prepared by scraping the edges and treating with a polymer sealant to eliminate leaks during development, and by cutting mobile-phase inlet and solvent outlet channels at appropriate positions. The Chrompres instruments allow linear development distances of 18 or 36 cm on a 20 × 40 cm TLC plate in the on-line mode, plus off-line circular development, for which no plate preparation is required for a maximum separation distance of 9 cm. Special plate preparation is required for circular or anticircular development over longer distances. Linear and circular OPLC are suitable for development of several plates simultaneously (parallel connected OPLC), or serial combination of plates is possible (long-distance OPLC). Different types of layers can be employed for a single analysis in these multilayer OPLC methods. The Personal OPLC BS 50 is a newer commercial OPLC instrument. Although OPLC has been the most used FFPC method, its reported practical applications have been quite limited.

High-pressure planar liquid chromatography (HPPLC) is a radial OPLC method that has been described but not widely used because of the unavailability of a commercial instrument. A single sample is applied to the center of the layer, and the mobile phase is delivered to the same point using up to 200 bar external pressure. In-flow sample injection is also possible. The method allows transfer of capacity factor (\(k'\)) data to HPLC as well as coupling of HPLC and planar chromatography.

7 ZONE DETECTION

After development with the mobile phase, the plate is dried in a fumehood and heated to completely evaporate the mobile phase. Separated compounds are detected on the layer by their natural color, natural fluorescence, quenching of fluorescence, or as colored, UV-absorbing, or fluorescent zones after reaction with an appropriate reagent (post-chromatographic derivatization). Although dependent upon the particular analyte and the detection method chosen, sensitivity values are generally in the nanogram range for absorbance and picogram range for fluorescence.

Layers are frequently heated after applying the detection reagent in order to accelerate the reaction upon which detection is based. Heating is carried out with a hair drier in a fume hood, in an oven, or with a TLC plate heater. The plate heater, which contains a 20 × 20 cm flat, even heating area, a grid to facilitate proper positioning of TLC and HPTLC plates, programmable temperature between 25 and 200 °C, and digital display of the actual temperature, provides the most consistent heating conditions.

Compounds that are naturally colored are viewed directly on the layer in daylight, while compounds with
native fluorescence are viewed as bright zones on a dark background under UV light. Viewing cabinets incorporating shortwave (254 nm) and longwave (366 nm) UV lamps are available for inspecting chromatograms in an undarkened room.

Compounds that absorb around 254 nm, particularly those with aromatic rings and conjugated double bonds, can be detected on an “F-layer” containing a phosphor or fluorescent indicator (often zinc silicate). When irradiated with 254 nm UV light, absorbing compounds diminish (quench) the uniform layer fluorescence and are detected as dark violet spots on a bright background.

Universal or selective chromogenic and fluorogenic liquid detection reagents are applied by spraying or dipping the layer. Various types of aerosol sprayers and dip tanks are available for manual operation. For safety purposes, spraying is carried out inside a laboratory fume hood or commercial TLC spray cabinet with a blower (fan) and exhaust hose. Dipping is usually the best method for reproducible results, and the most uniform dip application of reagents can be achieved by using a battery-operated chromatogram immersion instrument, which provides selectable, consistent vertical immersion and withdrawal speeds of 30–50 mm s\(^{-1}\) and immersion times of 1–8 s for plates with 10 or 20 cm heights. This mechanized dipping device can also be used for prewashing TLC plates prior to initial zone application, impregnation of layers with reagents that improve resolution or detection prior to initial zone application and development, and for postdevelopment impregnation of chromatograms containing fluorescent zones with a fluorescence enhancer and stabilizer, such as paraffin. A few detection reagents (HCl, sulfuryl chloride, iodine) can be transferred uniformly to the layer as vapors in a closed chamber.

8 DOCUMENTATION OF CHROMATOGRAMS

TLC separations are best documented by photography or video recording. Commercial systems for photodocumentation contain instant and conventional film cameras and associated lighting accessories for photography of colored, fluorescent, and fluorescence-quenched zones on TLC plates in shortwave, midrange, and longwave UV light and in visible light. A commercial video documentation system includes visible and UV lighting, a video or digital camera with zoom lens, monitor, and video printer. The system can also be extended to include data storage on a personal computer. A cabinet is available to house the photographic and video instruments for use in an undarkened room.

The latest technology for documentation of TLC plates involves computer scanning of the spots on the plate. The equipment required includes a computer, scanner, and monochrome or color printer. Computer scanning can be used only for visible spots, and not for those that are fluorescent or quench fluorescence.

9 ZONE IDENTIFICATION

The identity of TLC zones is obtained in the first instance by comparison of \(R_f\) values between samples and reference standards chromatographed on the same plate, where \(R_f\) equals the migration distance of the center of the zone divided by the migration distance of the mobile-phase front. Identity is more certain if a selective chromogenic reagent yields the same characteristic color for sample and standard zones, or if an \(R_f\) match is obtained in at least two TLC systems with diverse mechanisms, e.g. silica gel normal phase and C-18 bonded silica gel reversed-phase. Comparison of standard and sample in situ ultraviolet/visible (UV/VIS) absorption or fluorescence emission spectra, obtained by using the spectral mode of a densitometer, can also aid identification, but these spectra often contain inadequate structural information for complex mixtures. Identity can be confirmed by application of combined TLC-spectrometry methods described in section 11.1.

10 QUANTITATIVE ANALYSIS

10.1 Nondensitometric Methods

Quantification of thin-layer chromatograms can be performed after manually scraping off the separated zones of samples and standards and elution of the substances from the layer material with a strong, volatile solvent. The eluates are concentrated and analyzed by use of spectrometry, GC, HPLC, or some other sensitive microanalytical method. This method of quantification is laborious and time-consuming, and the difficulty in recovering samples and standards uniformly is a major source of error. Although its importance has declined relative to densitometry, the indirect scraping and elution quantification method is still widely used, e.g. for some drug assays according to the US Pharmacopoeia.

Direct TLC semiquantitative analysis can be performed by visual comparison of sample spot intensities with the intensities of reference spots developed simultaneously on the same layer. For this comparison, the bracketing method is used in which standard spots with concentrations equal to, greater than, and less than the expected
sample concentration are placed on either side of duplicate sample spots. The concentrations of samples and standards should lie within the linear response range of the detection method. The use of TLC for compliance screening of drug products is an important example of this approach.

10.2 Densitometric Evaluation

Most modern HPTLC quantitative analyses are performed by in situ measurement of the absorbance or fluorescence of the separated zones in the chromatogram tracks using an optical densitometric scanner with a fixed sample light beam in the form of a rectangular slit. The length and width of the slit are selectable for optimized scanning of zones with different dimensions. The densitometer measures the difference between the optical signal from a zone-free background area of the plate and from the calibration standards and sample zones. With automated zone application, precision ranging from 1% to 3% RSD is typical for densitometric analyses.

The plate is mounted on a moveable stage controlled by a stepping motor, which allows each chromatogram to be scanned, usually in the direction of development. Single-beam geometry is most often used and gives excellent results when high-quality plates and mobile phase produce compact, well-separated zones. A schematic diagram of a single-beam scanner arranged for measurement of absorption in the reflectance mode is shown in Figure 4. A tungsten–halogen lamp is used as the source for scanning colored zones in the 400–800 nm range (visible absorption) and a deuterium lamp for scanning UV-absorbing zones directly or as quenched zones on F-layers in the 190–400 nm range. The monochromator used with these continuous wavelength sources for TLC is most common for data processing and automation of control of the scanning process in modern instruments. With a fully automated system, the computer can carry out the following functions: data acquisition by scanning all plate tracks following a preselected geometric pattern with control of all scanning parameters; automated peak searching and optimization of scanning for each fraction located; multiple wavelength scanning to find, if possible, a common wavelength at which all substances can be quantified or the wavelength of maximum absorbance.

---

of each compound, to optically resolve fractions incompletely separated by TLC, and to identify fractions by comparison with stored data through pattern recognition; baseline location and correction; computation of peak areas and/or heights of samples and co-developed standards and processing of the analog raw data to quantitative digital results, including calculation of calibration curves by linear or polynomial regression, interpolation of sample concentrations, statistical analysis of reproducibility, and presentation of a complete analysis report; and storage of raw data on disk for later reintegration, calibration, and evaluation with different parameters.

Because of light scattering from the sorbent particles, a simple, well-defined mathematical relationship between the amount of analyte and the light signal has not been found. Curves relating absorption signal (peak height or area) and concentration or weight of standards on the layer are usually nonlinear, especially at higher concentrations, and do not pass through the origin. Modern integrators and computer software programs can routinely perform linear or polynomial regression of the calibration data, depending on which is most suitable. Fluorescence calibration curves are generally linear and pass through the origin, and analyses based on fluorescence are more specific and 10−1000 times more sensitive than those employing absorbance. Because of these advantages, compounds that are not naturally fluorescent are derivatized before or after chromatography to allow them to be scanned in the fluorescence mode if an appropriate reagent is available. However, absorbance in the 190−300 nm UV range has mostly been used for densitometric analyses.

Validation procedures for quantitative analysis are in some aspects very similar to those for HPLC and GC, with additional considerations related to procedural aspects specific to TLC. Protocols for validation of TLC results, especially for pharmaceutical analysis, are available in the literature. Some densitometers include automatic instrument validation programs in their software.

Video densitometers (image processors) are an alternative to the optical/mechanical scanners. Video densitometry is based on electronic point-scanning of a stationary plate using an instrument composed of UV and visible light sources, a charge coupled device (CCD) camera with zoom capabilities, and a computer with imaging and evaluation software. Video scanners have advantages including rapid data collection and storage, simple design with virtually no moving parts, easy operation, and the ability to quantify 2-D chromatograms, but they have not yet been shown to have the required capabilities to replace slit scanning densitometers. Current video scanners can function only in the visible range to measure colored, fluorescence quenched, or fluorescent spots. They lack the spectral selectivity and accuracy based on the ability to scan with monochromatic light of selectable wavelength throughout the visible and UV range (190−800 nm) that is inherent in classical densitometry, and they cannot record in situ spectra.

11 SPECIAL TECHNIQUES

11.1 Thin-layer Chromatography Combined with Spectrometric Methods

11.1.1 Mass Spectrometry

The identity of TLC zones can be confirmed by MS analysis. A zone can be scraped out of the layer, eluted from the sorbent, and transferred to the mass spectrometer as a discrete sample. Alternatively, the sample is not separated from the scraped sorbent and both are introduced into the spectrometer source on a direct insertion probe. Desorption methods include volatilization from a heated probe tip, laser ablation, or particle beam sputtering. Ionization techniques that have been used are electron impact (EI) for stable, volatile analytes, while less volatile or unstable analytes can be ionized by chemical ionization (CI), secondary ion mass spectrometry (SIMS), fast atom bombardment (FAB) or liquid secondary ion mass spectrometry (LSIMS) after mixing the sorbent with a suitable liquid matrix (e.g., glycerol). An alternative instrumental approach uses probes or plate scanners specifically designed to measure separated TLC zones. A sophisticated device for 2-D imaging of TLC plates using LSIMS has been described, as well as applications of TLC/tandem MS (TLC/MS/MS) to a variety of compound classes.

11.1.2 Infrared Spectrometry

Zones can also be confirmed by combining TLC with FTIR. Transfer techniques involve solvent extraction of the zone from the layer to an infrared (IR)-transparent pellet or powder (KBr). The most common in situ method is diffuse reflectance infrared detection (DRIFT), which has been used with silica, alumina, cellulose, and reversed-phase layers for identifications at the 1 μg level. Background absorption by the sorbent (3700−3100 and 1650−800 cm−1 for silica gel) must be subtracted from the sample spectrum; the resulting difference spectrum of the analyte may not match a solution spectrum in terms of absorption band positions and shapes because of interactions between the compound and sorbent. Sensitivity limits are high (ca. 1−10 μg per spot), but quantification is possible for compounds that do not absorb UV radiation or are not detectable by derivatization reagents.
11.2 Direct Coupling of Thin-layer Chromatography and High-performance Liquid Chromatography

TLC and HPLC can be combined into a powerful multidimensional method with enhanced separation efficiency because the former is generally used with a normal phase mechanism and samples are separated by distance, while the latter is most often reversed-phase and samples are separated by time. On-line coupling is possible by depositing HPLC column effluent onto the surface of a moving plate. The deposited HPLC fractions serve as the origin for further TLC separation with different selectivity.

The amount of HPLC effluent reaching the plate must be minimized so that overloading does not reduce resolution and the layer material is not washed away. This is done by using effluent-splitting or microbore columns coupled with a solvent elimination interface.

11.3 Thin-layer Radiochromatography

Location and quantification of separated radioisotope-labeled substances on a thin layer requires the use of autoradiography, zonal analysis, or direct scanning with a radiation detector.

Autoradiography involves exposure of X-ray or photographic film to emissions from radioisotope zones to produce an image on the film. After exposure and development of the film, the radioisotopes are visible as dark spots, which can be quantified by measurement of their optical densities with a scanning densitometer.

Zonal analysis involves scraping radioactive zones from the plate, placing the sorbent in counting vials, adding scintillation fluid or cocktail to elute the radioactive components, and liquid scintillation counting.

The first radiation detectors for direct measurement of radioactivity on TLC plates were the radioscaners, which utilized a mechanically driven windowless gas-flow Geiger counter. Linear analyzers are superior to radioscaners because the components of one entire track of the plate can be simultaneously measured without mechanical scanning, and the instrument can be programmed to move the detector head automatically to any chosen position. Linear analyzers incorporate a position-sensitive windowless gas-flow proportional counter as the detector. The fill gas (e.g. argon–methane) is ionized when radioactive emissions from the TLC zones enter the detector, producing electrons. The electron pulses are detected electronically and stored in computer memory to provide a digital image of the distribution of radioactivity on the layer. Multiwire proportional counters (Digital Autoradiograph or microchannel array detector) are 2-D detectors based on a measuring principle similar to the linear analyzer, but they can detect all areas of radiation from a 20 x 20 cm layer simultaneously without moving a detector head. Bioimaging/phosphor imaging analyzers represent the latest and most advantageous technology for measuring radioactive TLC zones. The layer is exposed to a phosphor imaging plate that accumulates and stores irradiating radioactive energy from the zones.
The plate is then inserted into an image-reading unit and scanned with a fine laser beam. Luminescence is emitted in proportion to the intensity of the recorded radiation, collected by a photomultiplier tube, and converted to electrical energy to produce an instrumental readout. Resolution, linear range, and sensitivity are equal to, or better than, those of the other detection methods.

Thin-layer radiochromatography is especially important in drug and pesticide metabolism studies in plants, animals, and humans and in studies of the fate of labeled chemicals in the environment. The methods described above are mainly for qualitative detection, but some degree of quantitative information can be obtained.

11.4 Rod Thin-layer Chromatography with Flame Ionization Detection

Separation on thin, cylindrical quartz rods coated with sintered silica gel (Chromarods) has been combined directly with flame ionization detection (FID) for analysis of compounds lacking a chromophore functional group that can facilitate optical densitometry, such as hydrocarbons and lipids. The sample is applied to the bottom of the rod, and several rods are placed in a support frame, then the frame is placed in a development chamber. After development, solvent is removed from the rods by oven drying, and individual rods are automatically passed through the detector at constant speed. The organic compounds separated on the rods are ionized by the flame of the FID, and the ions generate an electric current proportional to the amount of each compound. The data obtained are processed in a manner similar to GC with the same detector.

12 APPLICATIONS OF THIN-LAYER CHROMATOGRAPHY

TLC can provide rapid, low-cost qualitative analyses and screening in order to obtain information, such as sample stability, purity, and uniformity, and to follow the course of a reaction, while instrumental HPTLC can provide accurate and reproducible (1–3% RSD) quantitative results. Samples that are difficult to prepare can be analyzed readily, and detection is especially flexible in the absence of the mobile phase and with a variety of parameters.

TLC has been applied in virtually all areas of analysis, including chemistry, biochemistry, biology, industry, agriculture, environment, food, pharmaceuticals, clinical studies, natural products, toxicology, forensics, plant science, bacteriology, parasitology, and entomology. Compound types to which TLC has been successfully applied include pharmaceuticals and drugs, neutral and polar lipids, organic acids, carbohydrates, amino acids, peptides, phenols, indoles, purines, steroids, synthetic and natural dyes, vitamins, inorganics, and chiral compounds. High and low (trace) levels of analytes can be detected, identified, and quantified.

Discussion of specific applications of TLC is beyond the scope of this article. The reading list provides sources of information on the analysis of all types of compounds and samples, as well as discussions on theory, techniques, and instrumentation. Especially recommended for information on applications are the Sherma–Fried Handbook of Thin Layer Chromatography, the Fried–Sherma Practical Thin Layer Chromatography book, the biennial reviews by Sherma in Analytical Chemistry, and the Camag “CBS”. The Journal of Planar Chromatography—Modern TLC, published in six issues per year by the Research Institute for Medicinal Plants (Budakalasz, Hungary) in cooperation with Springer Hungarica, Budapest, exclusively features research papers, short communications, and reviews in the fields of analytical and preparative TLC and HPTLC.

Mass Spectrometry: Overview and History

O. David Sparkman
California, USA

1 Introduction

Mass spectrometry (MS) is the study of matter through the determination of the abundance and the mass-to-charge ratio (m/z) of ions in the gas phase. The data of MS are mass spectra. The mass spectrum is a plot of relative intensities (which represent the ion abundances) on the ordinate versus the m/z values of the ions on the abscissa. The tools of MS are mass spectrometers. A mass spectrometer consists of a sample-inlet system, a device for getting ions into the gas phase (the ion source), a method of separating the ions according to their m/z values (the m/z or mass analyzer), and a means of detecting the ions after they have been separated (the detector). The ions are separated and detected in the absence of other substances (i.e. in a high vacuum). Therefore, another significant component of a mass spectrometer is the vacuum system (Figure 1). In the mass spectrometers of the latter half of the 20th century and those of the 21st century, sample introduction, ionization, ion separation and detection, and data analysis are all done through the use of computers, which have become as integral to the mass spectrometer as any of its other components.

There are no limits to the types of matter that can be studied with MS. MS was originally used to determine the existence of the stable isotopes of the elements in the periodic table.\(^{(1)}\) [The word isotope was suggested by Frederick Soddy (1877–1956) as a student and collaborator of Ernest Rutherford at McGill University in Montreal, Canada, in 1913. Isotopes are different forms of the same element that have the same atomic number, but differ in their relative atomic mass due to a difference in the number of neutrons present in the nucleus of the atom. The word is derived from the Greek words isos (equal) and topos (places), ‘having the same place’ in the periodic table.]

MS has been used as a preparative technique \(^{(2)}\). It is also used for the identification and quantitation of various organic substances from the simplest gases such as methane and halomethanes to complex biomolecules such as proteins, oligonucleotides, and noncovalent complexes. Today, MS plays an important role not only in organic and biochemistry but also in inorganic chemistry such as the determination of metal contaminants in silicone wafers, drinking water, soils, industrial waste, etc. Mass spectrometers are not only found in analytical laboratories but also inside the helmets of space suits (to determine the level of gases that may pose a hazard), in tanks and other battlefield vehicles and on ships and aircraft (to detect the presence of chemical and biological warfare agents), and as more conventional field-portable instrumentation (for use at crime scenes, hazardous
The concept of MS is to form ions from a sample, separate the ions based on their mass-to-charge ratio (this can be considered to be the same as the mass because the ion has only a single charge in most cases), and measure the abundance of the ions. In modern MS instrumentation used in environmental analyses, all of the functions (ionization separation of the ions, rate of data acquisition, detection of the ions, and storage of the data) are under computer control. Gaseous molecules are ionized in the ion source to form molecular ions. Some of the resulting molecular ions will fragment. The molecular and fragment ions are accelerated into a mass analyzer (mass analyzer and mass filter are used interchangeably). By various processes, ions of differing \( m/z \) values pass through the mass analyzer one at a time to reach the detector. When the ions strike the detector, they are converted into an electrical signal which, in turn, is converted into a digital response that can be stored by the computer. (Reproduced by permission from O.D. Sparkman, ‘Mass Spectrometry’, in Encyclopedia of Environmental Analysis and Remediation, ed. R.A. Meyers, Wiley, New York, 1998.)

Two factors make MS one of the most powerful analytical chemistry techniques in use today. The first is the simplicity of MS. The analytes are characterized by “…the mass of their molecules and the masses of the pieces of their molecules”(3). Unlike the spectroscopic techniques that rely on the absorption of specific energies of electromagnetic radiation, there is no knowledge of esoteric characteristic wavelengths of absorption or resonance frequency of atoms required to deal with resultant data. The second factor is that MS yields more information about the composition and structure of a molecule from less sample than any other analytical technique. MS is different from the other various spectrometries in that it deals with analytes one molecule at a time rather than the behavior of the total sample. The only negative aspect of MS is that the sample is consumed by the analysis [with the exception of Fourier transform mass spectrometry (FTMS)]; however, the sample size required is small enough to make this particular disadvantage insignificant. MS has been used to determine the mass of a complete protein from attomole quantities(4) and to quantitate unambiguously identified subpicogram amounts of the pesticide malathion on orange peel.(5) It is used to determine the age of artifacts [isotope-ratio mass spectrometry (IR MS)], contamination of the surface of metal and composite airplane wings [secondary ion mass spectrometry (SIMS)], and the components that give fresh-baked bread its delightful aroma. The list of applications is endless.

Another important distinguishing characteristic of MS is that it deals with the mass of the isotopes of the individual elements rather than the atomic weight of the elements. See Note 1 at the end of the article.

The field of MS was originally referred to as mass spectroscopy by Sir Francis William Aston in 1920 (English Nobel Laureate in Chemistry, 1922; 1877–1945; one of the founding fathers of MS),(6) who called his instrument a mass spectrograph because it had an arrangement of the electric and magnetic fields, used to separate the ions, that was analogous to that of an achromatic set of prisms without lenses, which produced a spectrum of lines such as an optical spectrograph. Mass spectroscopy became the all-encompassing term for the use of mass spectrographs (instruments that focused ions on to a plane for detection on a photographic plate or an array detector) and mass spectrometers (instruments that focus ions to a point for electrical detection one \( m/z \) value at a time) as well as the studies of isotopic abundances, precise mass determination, analytical chemical use, appearance potential, etc. However, the term mass spectroscopy is too broad and is no longer recommended. The preferred term for techniques involved with the measurement of ions according to their \( m/z \) values and their abundances is MS.

Over the last half-century, the field of MS has been extensively reviewed. Other than from an historical perspective, only the more recent general references are of value.(7–9) This article reviews MS from an historical perspective as opposed to the technology of the instrumentation and the utility of the applications.

The field of MS is discussed in terms of ion-separation methods, ionization techniques, or applications. All of these are extensively covered either in this section of the Encyclopedia or in one of the Applications sections. An important aspect of the successful use of an analytical technique is a clear understanding of the method by which the data are acquired. It is therefore worthy of mention as to sources of extensive and definitive information on \( m/z \) analyzers [magnetic-sector,

References provide a seminal understanding of the
physics of ion-separating techniques employed by these individual analyzers.

The literature sources for the understanding of ionization techniques are somewhat less specific. The important aspect of electron ionization (EI), which is the technique most often used with gas chromatography/mass spectrometry (GC/MS), is understanding the fragmentation mechanisms that result in the mass spectra. This understanding is achievable through a series of excellent references or courses available from the American Chemical Society (ACS) or the American Society for Mass Spectrometry (ASMS). An important aspect of chemical ionization (CI), which is the technique most often used to obtain molecular weight information of a compound whose EI mass spectrum does not exhibit a molecular ion peak or that has some degree of volatility but is best separated by liquid chromatography/mass spectrometry (LC/MS), is the choice of the appropriate ionization compound (reagent). In order to obtain EI and CI spectra of some compounds, it may be necessary to form volatile derivatives.

The desorption/ionization (DI) technique of electrospray (ES) is still evolving. There are numerous descriptions of the mechanism involved in getting ions from the solution into the gas phase. The other current popular DI technique, matrix-assisted laser desorption/ionization (MALDI), requires less of an understanding of the ionization mechanisms but more of an appreciation for the sample preparation (the matrix). Other DI techniques such as fast atom bombardment (FAB), field desorption (FD), SIMS, and desorption chemical ionization (DCI) will be reviewed in this article and/or other articles in the Encyclopedia.

At this time, there is not a good single reference for the general technique of LC/MS; however, because of its maturity, GC/MS methods and techniques have been well elaborated. MS receives extensive coverage in both the fundamentals review and the applications review

Figure 2 A partial time line of the history of MS. (Adapted with permission from Siuzdak.)
issues, which appear in alternating years, of *Analytical Chemistry*.

## 2 HISTORY

The history of MS is graphically chronicled in Figure 2, which is an adaptation from Gary Siuzdak’s History of MS page. Siuzdak’s Web site also contains literature references for many of these events.

MS had its embryogenesis with the report of the German physicist Eugene Goldstein (1850–1930) at the Berlin Observatory that luminous rays in a discharge tube containing gases at low pressure emerged in straight lines from holes in a perforated metal disk used as a cathode. He called the rays Kanalstrahlen (canal rays). This report has been referred to as the first MS paper although the terms mass spectrum and mass spectrograph were suggested by Aston ca. 1920, and mass spectrometer was a term first used by two well-known early pioneers of MS, William R. Smythe (US scientist) and Josef Heinvich Elizabeth Mattauch (Austrian physicist), ca. 1926.

In 1895, the suggestion of the French physicist Jean Baptiste Perrin (1870–1942) that these rays were associated with a positive charge was confirmed by the German physicist and 1911 Nobel Laureate Wilhelm Wien (1862–1928). Wien showed that these rays were deflected in a magnetic field and that their behavior could be studied by the combined effects of magnetic and electric fields.

The first instrumentation for the measurement of masses of charged particles was described in a lecture by Sir Joseph John Thomson entitled ‘Cathode Rays’ on April 30, 1887, at the Friday Evening Discourses in Physical Science held at the Royal Institution in London (Figure 3a and b). This particular event was Thomson’s announcement of the discovery of the electron for which he was awarded the 1906 Nobel Prize in Physics. Thomson called the Kanalstrahlen rays rays of positive electricity. Thomson became aware of the potential for these as tools in the analysis of matter and published the first MS book: *Rays of Positive Electricity and Their Application to Chemical Analyses*. Thomson’s discovery and initial instrument were followed by the development of a sector-based (magnetic and electric) mass spectrograph ca. 1911, which resulted in Francis William Aston (one of Thomson’s collaborators at the Cavendish Laboratory) being awarded the 1922 Nobel Prize in Chemistry (Figure 4). This instrument employed velocity focusing. Aston’s 1920 paper, ‘The Constitution of Atmospheric Neon’, is considered the first paper in applied MS.

During the same period that Aston was pursuing the mass spectrograph, the Canadian–American physicist Arthur Jeffery Dempster (1886–1950), in an independent effort, developed a single magnetic-sector instrument that employed direction focusing of constant energy...
of oxygen that led to the difference in the physical and chemical definitions of the atomic mass unit (amu). Prior to this time, there had been a single definition of the atomic mass unit, which was that 1 amu was equal to 1/16 the atomic weight of oxygen. Aston defined the amu as 1/16 the mass of the most abundant naturally occurring stable isotope of oxygen, $^{16}$O. This definition resulted in a factor of 1.000275 difference between the standards, which was resolved by the replacement of the amu with the unified atomic mass unit (u or, in current terms, Da, the dalton) in 1962. Although unsubstantiated, it has been reported that Aston once said, ‘Once all the isotopes of the elements in the periodic table had been determined, there would no longer be a need for MS’.

As the users of these early mass spectrometers (always custom built) began to complain about the presence of ions that did not correspond to their analytes, the organic chemists realized this was coming from organic impurities in the samples. This led to a growing interest on the part of the organic chemist. Commercial instruments began to appear, and MS became an essential tool in the petroleum industry. The 1940s saw the birth of organic MS. Not all organic compounds were suitable for mass spectral analysis. Since ions were separated in the gas phase, they had to be formed in the gas phase in this early instrumentation. This meant that the analyte had to be volatile and nonthermally labile.

While the development of the atomic bomb by the United States was underway, many of the developments in MS became shrouded in secrecy owing to the key role that it played in this development and the actual implementation of the bomb (Figure 6a and b).\(^2\)

In the 1950s, a great deal of research took place on MS instrumentation. This led to several different ways of separating the ions according to their $m/z$ values. Although the sector-based instruments (mass spectrometers are usually described by the way which ions are separated according to their $m/z$ values) dominated the analytical chemistry laboratories, the desire for lower cost, simpler to use instruments led to the discovery and development of the TOF mass spectrometer, followed by the TQ, the ion cyclotron resonance (ICR), and eventually the QIT mass spectrometer. The pioneering efforts of this period led to the instruments of predominant use today. This same era was the beginning of the commercial MS industry with manufacturers appearing in the UK, Germany, and Japan to join those already established in the USA.

The gas chromatograph (GC), developed ca. 1952 by A. James and A. Martin,\(^3\) was interfaced to the mass spectrometer in the mid-1960s.\(^3\) This development allowed mixtures of organic analytes to be separated into relatively contaminant-free individual compounds that were delivered to the mass spectrometer in the gas phase.

A potential difference between the sample holder and the first slit ($S_1$) provided the ion acceleration.\(^6\)
substructures. New ionization techniques such as chemical and field ionization (FI) were also developed in the 1960s to be able to directly determine the molecular weight of compounds whose EI mass spectra did not have a molecular ion peak.

The gas chromatograph–mass spectrometer (GC-MS) became one of the most widely used analytical instruments by organic chemists in the 1970s, and thus began the eventual dominance of the TQ mass spectrometer over the sector-based instrument that had ruled for the first 40 years of MS. With its lower price, more rapid spectral-acquisition ability, and ease of use compared with the sector-based instruments, the TQ mass spectrometer was ideally suited for GC/MS. In the late 1960s and early 1970s, new computer techniques were developed that resulted in easier methods of dealing with the GC/MS data. The triple-quadrupole m/z analyzer was developed to determine additional structural information on the fragment ions produced by EI and CI. The role of positive ions had dominated the MS of organic compounds; however, in the 1970s, the discovery of the formation of negative ions under CI conditions led to new levels of sensitivity in GC/MS.

The high-performance liquid chromatograph (HPLC) was interfaced to the mass spectrometer in the 1970s. This marriage was not as successful as that of the GC and the mass spectrometer. Owing to the volatile nonthermally labile requirement of the analyte (even though the analyte could be separated from the mobile phase of the HPLC), ionization was not always possible. The liquid chromatograph–mass spectrometer (LC-MS) remained a laboratory curiosity until the development of DI techniques. At the end of the 20th century, the LC-MS had become an even more prevalent instrument than the GC-MS. Part of the reason for this emerging dominance is the ability to form ions of analytes in the liquid chromatograph (LC) eluates using the atmospheric pressure ionization (API) technique of ES. The technique of LC/MS has also been popularized through the other API technique of atmospheric pressure chemical ionization (APCI). Unlike ES, APCI forms the ions in the gas phase. Although the ions must still be in the gas phase for their separation according to mass-to-charge ratio to take place, analytes that may not survive the rigorous temperature conditions of the GC required for their separation can pass through the LC process without harm and still have ions that end up in the gas phase. The API LC/MS techniques do not provide the same level of structural information as can be obtained from the gas-phase EI process; however, structural information can be obtained through techniques of mass spectrometry/mass spectrometry (MS/MS) and using in-source collisionally activated dissociation (CAD), which are also fairly recent developments.

Figure 6 (a) An illustration of the Calutron’s second-stage ß units used at Oak Ridge National Laboratory to produce weapons-grade 235U from the first stage. The origin of the name for this preparative instrument is ‘CalU’ from the University of California, Berkeley, and the Greek suffix ‘tron’, which means instrument – Calutron. ORNL Drawing 42951. (b) Photograph of two workers cleaning one of the Calutron’s vacuum system tank liners at the Y-12 Electromagnetic Separation Plant, previously known as the Clinton Engineering Works. GC/MS was limited in its usefulness by the plethora of data produced until the development of the minicomputer later in that same decade. The 1960s were also the period that MS of organic compounds began to be explained by organic reaction mechanisms, which allowed for a more detailed interpretation of the mass spectral data resulting from the EI of an organic compound and the prediction of fragment ions based on the presence of elements and...
The late 1980s and the 1990s constitute the period during which the DI technique of MALDI developed and became a routine tool. ES is also referred to as a DI technique. These two DI techniques allow for transfer of ions formed in solution (ES) or in a solid (MALDI) to the gas phase for \( m/z \) analysis. The DI techniques have eliminated the volatile nonthermally labile requirements for analytes allowing for the characterization of synthetic organic polymers and biopolymers by MS. In this same time period, inductively coupled plasma (ICP) ionization for inorganic substances in solution was linked with MS. In addition, other DI techniques such as SIMS has become a routine tool in the analysis of both organic and inorganic substances on the surfaces of substances important to the material scientist. These last two techniques have given MS a rebirth in the field of inorganic analyses.

Since the determination of stable isotopes of the elements of the periodic table by MS, the widest impact of the analytical technique has been in organic chemistry. MS still plays an important role in inorganic chemistry and geochemistry, but the major discoveries and uses are in the organic field.

### 2.1 Beginning to the 1940s

At the time Thomson reported his parabolic instrument using electrical and magnetic fields, he referred to the particles that are known as electrons as corpuscles (small negatively charged particles from which atoms were built up). This made Thomson the first mass spectrometrist to generate neologisms (unfortunately, a trait not uncommon to modern mass spectrometrists) that later fell into disuse (rays of positive electricity and corpuscles). With the collaboration of Aston, Thomson’s apparatus was improved to the extent that these rays of positive electricity (ions of positive charge) could be separated according to their mass-to-charge ratios. Their joint efforts led to the 1910 improvements of the Thomson positive-ray tube, which was used in the 1912 discovery of the two stable isotopes of neon. This report was the first of nonradioactive isotopes\(^{31}\) and had a profound effect on the development of atomic and nuclear theory.

After World War I, Aston returned to the Cavendish Laboratory, continued to collaborate with Thomson, and dedicated his career to the separation of the two isotopes of neon and the proof of their existence beyond doubt. This work produced continued improvements of Thomson’s apparatus and culminated in the development of the mass spectrograph. Thomson is the discoverer of MS, and Aston is the developer of the mass spectrometer.

In the early part of the 20th century, the technique of positive-ray analysis took two different paths: (1) that pursued by Aston, which was the accurate determination of mass; and (2) that pursued by Dempster (in the USA), which was more suited for the determination of the abundance of the ions. Aston’s instrument results in the ions striking a photographic plate that is on a focal plane. Aston called this a mass spectrograph and also coined the term mass spectrum. The Dempster instrument focused the ions of one \( m/z \) value at a time on a point so that they could be converted to an electrical signal that is then amplified and measured. Through the ability to record accurate ion abundances, Dempster was able to show that seven out of every 1000 uranium atoms were the isotope with a nominal mass of 235. Thomson, Aston, and Dempster (Figure 7a–c) are considered to be the founding fathers of MS.\(^{10}\)

Aston foretold the impact of MS on atomic theory in his 1922 Nobel address where he forecast both nuclear bombs and power plants based on the future use of the energy in an atom’s nucleus.

Building on the developments of the founding fathers of MS, others began to advance the field in the period just prior to World War II. During this period, Dempster developed EI. [EI was originally called electron impact. This is a process by which gas-phase molecules at a pressure of \( \times 10^{-3} \) Torr are ionized by a beam of electrons, produced by a hot wire (filament), that have been accelerated by 70 V (i.e. 70 eV).] EI is used in modern mass spectrometers where analytes are in the gas phase. There has been more study of EI processes and fragmentation than all others types of mass spectral ionization techniques combined. All of the large archives of mass spectral data contain EI spectra obtained at 70 eV. Dempster also developed the spark-source and vacuum-vibrator techniques used in the analysis of inorganics in solids.

During this pre-World War II period and after the significant developments of the Aston/Thomson/Dempster era, most of the advances in MS were made in physics. A series of seminal articles were presented by Roboz (p. 491).\(^{10}\) These papers began to appear in the early 1920s and continued through the mid-1930s. After that time, there were few references, if any, to MS because of its strategic importance to the war effort both in the area of organic chemistry and nebular weapon development.

One important aspect of the use of MS came about through the isolation of heavy water and the discovery of deuterium by Harold Clayton Urey (1893–1981), a US chemist at Columbia University, New York, in 1934. This accomplishment resulted in Urey’s receipt of the Nobel Prize for Chemistry in 1934. David Rittenberg, one of the doctoral students in Urey’s laboratory at the time of this discovery, studied some of the thermodynamic properties of compounds containing these newly discovered isotopes. Shortly after receiving his PhD in 1934, Rittenburg joined the Biochemistry Department at Columbia University, where he remained until his

(Courtesy of the University of Chicago.\textsuperscript{10})
death in 1970. He and a departmental colleague, Rudolf Schoenheimer, began a study in 1935 of intermediate metabolism using stable isotopes. They were the first to use deuterium labeling to investigate the metabolism of amino and fatty acids. This original work of Rittenburg and Schoenheimer resulted in the ‘dynamic state of body constituents’ concept, which said that the apparent static state of many constituents results from rapid opposing reactions at nearly equal rates. Over the next 36 years, Rittenburg published over 200 papers. Many of the specifics of using stable isotope-labeled compounds in the determination of metabolic pathways is presented by Richard Caprioli, the last person to receive a PhD under the direction of Rittenburg.

The ability to use the difference in mass between an analyte and its analog labeled with a stable isotope of nitrogen, carbon, oxygen, and/or hydrogen has resulted in one of the primary uses of MS in the biological sciences. The labeled material can be used to determine which compounds resulted from the metabolism of an ingested drug or nutrient. Labeled analogs can be used as internal standards, which result in lower detection limits owing to finite analyte-absorptive properties of a particular analysis. As internal standards, labeled analogs of an analyte will behave chemically and physically the same as the analyte. This means reduced errors in quantitation due to internal standard effects. The most difficult step in the use of stable labeled isotopes is the preparation of the label compound. These selectively labeled compounds have been extensively used to determine the mechanisms of fragmentation. One of the pioneers in this area was the Swedish medical scientist Einar Stenhagen (1911–1973), who received several patents on the synthesis of labeled compounds of biological interest. He also was granted a patent for the jet separator, the most popular device for the interface of high-flow packed columns and large-bore, capillary GC columns, which have high optimum flow rates (15–30 mL min \(^{-1}\)) to a mass spectrometer.

In spite of the extensive contributions by Rittenburg based on the use of MS, he only receives token mention in some of the early references on MS and none in others. This lack of reference is one of the reasons for the importance of the two early books edited by George Waller at Oklahoma State University.

It was not until the 1940s that commercial instruments began to appear. All the instruments used in isotope-labeling studies were built as one-of-a-kind research curiosities by their user or colleagues of these users. The first of these commercial instruments was the Consolidated Engineering Corporation’s (Pasadena, CA) CEC 21-101. Until that time, mass spectrometers were custom built by researchers such as Dempster. Among this group of early innovators of the instrumentation were Dempster, Smythe, Mattauch (in cooperation with Richard Herzog in Germany ca. 1934–1936), and the American physicist Alfred Otto Carl Nier (1911–1994), who was a key figure in the Manhattan project. One of the two most popular geometries for a double-focusing instrument was a result of this era, the Mattauch–Herzog mass spectrograph, with ion optics worked out by Herzog and built by Mattauch in Germany. The other is the Neir–Johnson geometry developed by Neir and Edger G. Johnson, a master’s degree graduate student, after World War II, ca. 1948.

One of the hindrances to the development of MS was the crude state of knowledge about the production of a vacuum. The low-pressure requirement of MS was such that poor vacuum technology resulted in hours of frustration. One very significant improvement that came out of the war research into MS was advances in vacuum systems.

The Consolidated Engineering company was the first commercial manufacturer of mass spectrometers. This pioneer mass spectrometer manufacturer was founded by Herbert Hoover, Jr, in 1937 as the engineering and manufacturing subsidiary of the United Geophysical Company to develop a mass spectrometer to locate oil deposits by detecting hydrocarbon gases emitting from the ground. The company had close connections with the California Institute of Technology and the petroleum industry. The initial project was a failure due to the ubiquitous nature of methane in ground-seepage gas. However, the instrument was useful as a replacement for a distillation analysis used to detect light-end hydrocarbon gas mixtures in the production of aviation fuel. The company was later renamed the Consolidated Electrodynamic Corporation because of restrictions of the use of the words ‘engineering’ and ‘engineer’ in the state of Texas to those that were licensed by the state as engineers. The company was then sold to Bell & Howell and later to DuPont. While under the control of DuPont, the manufacture and support of mass spectrometers was terminated.

The CEC 21-101 had an \(m/z\) range of 16–72, and it was able to produce a spectrum over this range of a mixture of C\(_1\)–C\(_3\) hydrocarbons in 20 min. This initial design was refined into several subsequent models culminating in the CEC 104, which had a unit-resolving power over its entire \(m/z\) range to 700. The last of these instruments was manufactured in 1965. The last instrument was taken out of service by Exxon in 1997.

One of the hindrances to the advancement of MS after the introduction of the CEC 21-101 was a requirement in the CEC sales agreement demanding that all data made available be made available to CEC. This requirement was not well received in the competitive petroleum industry and led to an all-glass instrument
that was produced by Westinghouse Electric Corporation (the Type LV, a 90° sector instrument as opposed to the CEC 180° instrument) in collaboration with Humble Oil and Refining and several other oil companies. These Westinghouse instruments were some of the first used outside of the temples of MS (University of Minnesota, Princeton, Harvard, University of Chicago, and Cal Tech) for the study of organic compounds. After the end of the war, CEC changed its information-sharing policy and went on to dominate the field of commercial MS through the 1960s. The end of the 1940s saw the beginning of the second era of MS.

It is interesting to note that the CEC 21-101 mass spectrometer was copied from Nier's 1918 instrument, which had an analyzer copied from Dempster's 1918 instrument. Nier built this instrument while studying with Kenneth T. Bainbridge at Harvard University. Unlike Dempster's 180° instrument, the Nier mass spectrometer had an ion source with both electric and magnetic fields. This instrument represented the birth of commercialization of academic research in MS.

2.2 The Birth of Organic Mass Spectrometry

Until World War II, MS had only a small role in organic chemistry. At the end of the war, advancements in MS had been largely confined to improvements in instruments to separate isotopes of elements and how to make these instruments suitable for the preparation of production quantities of isotopes that played a major role in atomic weapons production. There were only three books devoted to the subject of MS – one authored by Thomson and two by Aston. All three of these books had two editions. The first book to appear after World War II was G.P. Barnard's Modern Mass Spectrometry in 1953. This book was similar to those of Aston and Thomson in that it concentrated on the instrumentation and ion behavior. Treatment of applications was somewhat broader than that of Thomson or Aston, but still only of footnote quality and quantity. And keeping with that philosophy, there is only a brief mention of Rittenburg's use of MS.

Although MS continued to be primarily the privy study of the physicist, the role of the organic chemist began to emerge with a high degree of visibility. Several companies (CEC in the USA, AEI in the UK, Atlas in Germany, and Hitachi and JEOL in Japan) began the development of commercial instruments after World War II primarily for use in the analysis of organic compounds. This proliferation of manufacturers led to more users and a desire for people to discuss common experiences and problems. According to Seymour Meyerson, the first MS meeting, the symposium on mass, infrared (IR), and ultraviolet (UV) spectrometry, was held in the USA and organized by Rubber Reserve Company and the Petroleum Administration for War. The first review of mass literature appeared in Analytical Chemistry in January 1949. In this review, John Hipple of the National Bureau of Standards (NBS), Washington, DC, a Division of the United States Department of Commerce, pointed out that in Chemical Abstracts there had been 11 references to MS in 1943, 15 in 1944, 17 in 1945, 26 in 1946, and 40 in 1947. Hipple’s review had 165 citations as compared with that of Alma Burlingame in the same type of review published in 1998, which had 1551 citations divided into nine categories: Overview (5), Scope (173), Innovative Techniques and Instrumentation (364), IR MS (89), High-power Lasers in MS (51), Dissociation by Low-intensity IR Radiation (18), Polymers (61), Peptides and Proteins (264), and Oligonucleotides and Nucleic Acids (166).

September 6–8, 1951, were the dates for a symposium on MS in physics research, held in Washington, DC, as one of 12 symposia commemorating the sesquicentennial of the then NBS [now the National Institute of Standards and Technology (NIST)]. John Hipple organized this symposium in cooperation with the Office of Naval Research. Of the 36 presentations, only one pertained to the use of MS in organic chemistry: ‘Mass Spectra of Heavy Hydrocarbons’, by M.J. O’Neal, Shell Oil Company (Houston, TX). This presentation included spectra of aliphatic hydrocarbons and aliphatic hydrocarbons with aromatic substitutions. The remainder of the presentations revolved around instrumentation and ion physics.

Similar conferences were organized in the UK by the MS Panel of the Institute of Petroleum in 1950 and 1953. The proceedings of the second of these meetings, held October 29–31, 1953, at the Institute of Electrical Engineering in London with 200 people in attendance, were published. This conference consisted of five half-day sessions, with a total of 26 presentations. A commercial exhibition associated with the conference had four companies displaying computing equipment: British Tabulating Co., Ltd., Elliot Bros. (London), Ltd., Ferranti, Ltd., and International Business Machines (United Kingdom), Ltd., and two companies displaying mass spectrometers, Metropolitan–Vickers Electrical Company, Ltd., and Vacuum Industries Applications, Ltd. This conference, as could be guessed by the name of the organizer, was much more related to the use of MS in organic analyses.

The proliferation of mass spectrometer manufacturers led to the organization of ‘user meetings’ where people using the same types of instruments could gather and discuss common problems and tell of their new discoveries. One such user meeting organized jointly by CEC and General Electric Corporation at the 1952
meeting (third meeting) of the Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy (Pittsburgh, PA), sponsored by The Society for Analytical Chemists of Pittsburgh and The Spectroscopy Society of Pittsburgh, became the E-14 Committee (an educational committee) of the American Society for Testing and Materials (ASTM). Proceedings of the annual E-14 meeting have been published since 1961. At the 1969 E-14 Committee meeting in Dallas, TX, the membership formed the ASMS, which is the largest organized group of mass spectrometrists in the world today. After 1969, the published proceedings were under the ASMS name. See Note 2 at the end of the article.

As an outgrowth of the two meetings organized by the MS Committee of the Institute of Petroleum in the UK, an international MS meeting, the International MS Conference, began in 1958. There have been 14 of these triennial meetings. The first six meetings were held in the UK. Beginning with the seventh meeting (Florence, Italy), each succeeding meeting has been held in a different European country. The 15th International MS Conference is scheduled for Barcelona, Spain, in 2000.

The instrument manufacturers' user meetings are still significant, and there were at least 10 companies holding these meetings at the 1999 annual ASMS Conference on MS and Allied Topics.

In the early 1960s, John Beynon in the UK (1960) followed by Klaus Biemann in the USA (1962) published two of the classical books on MS of organic compounds: *MS and its Applications to Organic Chemistry* (46) and *MS: Organic Chemical Applications.* (47) These books were quickly followed by a series of books showing that mass spectral data could be related to mechanisms of organic reactions. (50) In addition to these important works pertaining to organic MS came another series of general-interest books from both American and British authors. Two of the most important were those authored in the US by Robert W. Kiser (Kansas State University, Lawrence, KS) (6) and John Roboz (Air Reduction Company, Inc., Murray Hill, NJ). (10) A book edited by George Waller (Oklahoma State University) was published in 1972, (59) *Biochemical Applications of Mass Spectrometry.* This book is the first book devoted to MS and biochemistry.

Through cooperation between those interested in MS for applications in organic chemistry and biochemistry such as Biemann and Beynon and the several instrument companies that were vying for the market, a number of improvements were made in the magnetic-sector mass spectrometer. These improvements included more rapid acquisition rates and the development of mass accuracy measurements that allowed the assignment of empirical formula to ions whose mass was determined to the nearest 10 millimass units. During these early phases of organic MS, the instruments were used as separation devices for mixtures such as the paraffin, olefin, naphtha, and aromatic (PONA) analyses used by the petroleum industry, in the determination of isotopically labeled compounds purified from complex biological mixtures, and in the determination of the structure of purified compounds.

The period after World War II also saw developments in nonmagnetic-field technologies to separate the ions. These developments resulted in the TOF, TQ, and QIT mass spectrometers. Details of these developments can be found in section 2.6.

### 2.3 Gas Chromatography/Mass Spectrometry – A Tremendous Success

Almost from the appearance of the first paper on gas chromatography, the organic mass spectrometrist saw the potential advantage of separating a complex mixture into nearly pure components followed by mass and structural analysis with no need for human intervention. Although the technique of GC/MS had the greatest potential for those in the biological science, the first published report of this interface that involved dilute analytes in an above-atmospheric-pressure gas being introduced into an instrument that operates at pressures as low as $10^{-10}$ Torr [pressures in high vacuum are referred to in Torr by most manufacturers of mass spectrometers. 1 Torr is equivalent to 1 mm of mercury or Pascal (Pa); 1 Torr = 133.322 Pa; 1 Pa $\approx$ 0.0075 Torr; 1 atm = 760 Torr or $1.013 \times 10^5$ Pa (exactly, by definition)] came from the bulk chemical industry – Dow Chemical in Midland, MI. (35, 36) This first effort used a TOF mass spectrometer because of its rapid spectral acquisition rate compared with a sector-based instrument and an oscilloscope fitted with a Polaroid camera to record the spectra. Less than 1% of the GC eluate was put into the mass spectrometer.

Three major hurdles had to be overcome in order for GC/MS to be an executable analytical technique: (1) the problem with the amount of gas expelled from the GC and the requirement for high vacuum in the mass spectrometer; (2) the need for rapid mass spectral acquisition to compensate for the ever-changing partial pressure of the analyte; and (3) the tremendous amount of data collected during a single GC/MS analysis.

Dealing with the pressure difference and the low analyte concentration in the GC eluate was undertaken by a number of different investigators. This work resulted in several different devices that are known as GC/MS separators. The most popular was the jet separator invented, and later patented, by Einar Stenhagen (Swedish medical scientist) and perfected by Ragnar Ryhage. (60) In addition, Jack Watson, while a PhD student of Klaus Biemann at Massachusetts Institute of Technology (Cambridge, MA), and Duane Littlejohn and Peter Llewellyn, at the
Varian Research Center in Palo Alto, CA, also developed separators.\textsuperscript{61,62} The Llewellyn separator enjoyed some commercial success but not to the same extent as that of the jet separator (Figure 8). As the use of capillary columns (50–250\,µm ID GC columns and flow rates of 1–2\,mL\,min\(^{-1}\) where the stationary phase is coated on the inner walls) replaced the packed columns of the 1960s and 1970s (2–5\,mm ID GC columns and flow rates of 20–30\,mL\,min\(^{-1}\) where the stationary phase is a high-boiling liquid coated on diatomaceous earth particles packed inside of the column), the need for these devices used to enrich the concentration of the analyte in the GC eluate passing into the mass spectrometer as well as reducing the total volume of gas introduced to the mass spectrometer was no longer needed. Jet separators are still used with larger diameter capillary columns (530–750\,µm ID), but the use of these columns is becoming less as new preconcentration techniques are developed.

Although the use of the TOF mass spectrometer appeared to resolve the problem of rapid data acquisition, there were other problems associated with this type of \(m/z\) analyzer that kept it from becoming a part of a successful commercial GC-MS. With the potential for GC/MS, the first efforts were put into interfacing existing instruments to the GC. None of these endeavors were very successful. As more investigation took place, it was found that GC/MS was as different from either gas chromatography or MS as these two techniques were from one another. The first commercial instrument built as a GC-MS was the LKB 9000 produced in Sweden by LKB Instruments in the mid-1960s. Other manufacturers produced a mass spectrometer with a GC inlet, but the LKB 9000 was neither a GC with a mass spectrometer as the detector nor a mass spectrometer with a GC inlet. LKB pioneered the technology required to remove the carrier gas from the GC eluate from packed columns (enriching the flow with analyte prior to introduction into the mass spectrometer: jet separator). The LKB 9000 was a single-focusing magnetic-sector instrument. To optimize it for GC/MS, special considerations were given to the vacuum system and the scanning of the magnetic field. In addition, emphasis was put on the detector system to allow for the rapid acquisition of data required for GC/MS analyses.

The first prototype LKB 9000 was delivered to George Waller at Oklahoma State University (Stillwater, OK) in 1964. The LKB 9000 did not address the issue of the amount of data that is acquired in a GC/MS analysis. This instrument used a light-beam oscillographic recorder to record the mass spectra. Spectra were manually selected for recording (Figure 9).

With the development of the minicomputer in the mid-1960s, it became possible to deal with the vast amount of data generated in a single GC/MS analysis. Before that time, acquiring spectra over a range of 200–250 \(m/z\) units every 2–3\,s in a GC analysis that lasted for 15–30\,min produced as many as 225,000 data points (mass spectral peaks in multiple spectra) that had to be dealt with manually. Data were typically acquired by using a multichannel analog recorder that increased the amount of data and the complexity in converting it to usable information. The paper used to record these data was usually light-sensitive and had a short life before the recorded images would fade into oblivion especially if exposed to fluorescent or sun light. This volume-of-data problem greatly reduced the number of samples that could be analyzed with a reasonable amount of effort. The minicomputer allowed for the automated collection of data. The generation of several different types of chromatograms was made possible by computer processing the \(m/z\) and intensity data recorded by the data system (DS). Sums of intensities for all the \(m/z\) values in each spectrum (total ion current) could be plotted versus the spectrum numbers to produce a reconstructed total ion current chromatogram. Intensities of specific \(m/z\) values, sums of \(m/z\) values, or ranges of \(m/z\) values could be plotted versus spectrum numbers to produce
reconstructed ‘mass chromatograms’. A DS typically could display bar-graph mass spectra (unit resolution and intensity data) for the data from individually acquired spectra. These bar-graph spectra would generally be normalized to the most intense peak (base peak) and could have peaks due to ions from substances other than the analyte (background) deleted. Even with these primitive abilities (by today’s standards), the number of samples that could be handled in a week increased by orders of magnitude.

GC/MS began to become a routine technology with the introduction of the TQ GC/MS instrument. The first commercial TQ GC/MS system was developed by Finnigan Corporation (San Jose, CA), now part of ThermoQuest. According to Bob Finnigan, one of the founders of Finnigan Corporation, in an Analytical Chemistry A-pages article, the first Finnigan 1015 GC/MS instrument (prototype) was delivered to Bert Halpern and Walt Reynolds at the Stanford Medical School Department of Genetics in January 1968. Two other prototypes were delivered to John Amy at Purdue University and Carl Djerassi at Stanford University. Based on the feedback from these initial installations, many improvements were made in the Model 1015, especially in the single-jet separator design that had been given to Finnigan by Stenhagen (the Ryhage jet separator used in the LKB 9000 was a dual-stage design), which took almost 2 years to perfect.

Bob Finnigan became aware of the power of GC/MS in combination with the results he saw from the DS designed and built by Reynolds and Tim Coburn at Stanford. Although Hites and Biemann had earlier reported a system to deal with the acquired data from a GC/MS system, the Reynolds and Coburn system for the TQ mass spectrometer along with a similar system for magnetic-sector instruments developed by Jack Holland and Chuck Sweeley at Michigan State University were the first DSs that actually controlled the mass spectrometer and also stored the data. The Stanford GC/MS DS led Finnigan to enter into an agreement with a new company, Systems Industries, Inc. (Sunnyvale, CA), to commercialize the Stanford system and become the first commercial GC/MS DS – the System 150. Finnigan accepted its first order for a computerized GC/MS system in 1968 from Evan Horning at the Baylor College of Medicine in Houston TX.

Initially, the System 150 was sold only by Finnigan Corporation. The data consisted of a Digital Equipment Corporation (DEC) PDP-8 minicomputer with 4K words (12-bit words) of core memory, a magnetic tape system (a LINC, Lincoln Laboratories at MIT, tape) designed specifically for the PDP-8, a standard ASR 32 teletype for input and output of text information as well as the ability to load programs through a punched paper tape, and a Houston Instruments digital plotter for the output of bar-graph mass spectra normalized to the most intense peak and reconstructed chromatograms (total ion current and mass). The DS had an interface that would convert digital instructions into analog signals used to tell the mass spectrometer which $m/z$ range to scan, the time interval for each scan, the total analysis time, the magnitude of the radiofrequency (RF) and direct current (DC) voltages for each individual $m/z$ value, and other factors associated with data as well as taking the analog data from the mass spectrometer that represented $m/z$ values (based on calibration with a compound that produced ions of known $m/z$ values) and ion abundances. These analog signals from the mass spectrometer were converted to digital values that were used to display the acquired data as spectra or reconstructed chromatograms. The computer and magnetic tape, along with the interface, were fitted into an electronics rack that was 19 in wide, 60 in high, and 30 in deep. The System 150 went on to be a general-purpose GC/MS DS sold by Systems Industries as well as several manufacturers of GC/MS instrumentation on an original equipment manufacturer (OEM) basis.

The System 150’s capabilities were expanded and refined through the use of third-party software such as the Biemann computerized library search of mass spectral databases and use of the Tektronic’s electronic storage terminal for graphical display (both developed at the Battelle Columbus Laboratories), and data analysis and acquisition software specific to sector-based instruments developed at Michigan State University. The System 150, later marketed by the French GC/MS manufacturer Nermag (originally Riber) as the RDS 400, also took advantage of new hardware features such as disk storage that replaced the slower and lower capacity magnetic tape systems. The Riber 400 remained a reliable and competitive GC/MS DS through the mid-1980s. Because all of the software was developed using the PDP-8’s assembly code and the system was capable of either acquiring or processing data, but not both at the same time on a single computer, it was very fast. It has only been in the last 2–3 years that GC/MS data processing has achieved the speed of the System 150/Riber 400, and this has been due to the very fast computers with extremely large amounts of random access memory (RAM).

There were two additional third-party DS companies that appeared in the late 1970s: INCOS (acronym for Instrument Company Operating System) and Teknivent Corporation. The INCOS DS was originally designed as a retrofit to sector-based instruments. The INCOS used a Data General minicomputer with a custom disk operating system called IDOS (another acronym) that allowed for simultaneous data acquisition and analysis. The data analysis features were unique with some rather spectacular graphics displayed on the Tektronic’s graphics
Figure 10 A partial display of the three dimensions of chromatographic/mass spectrometric data.

These graphics included a three-dimensional plot of the spectra along the z-axis, a spectrum number on the x-axis, and an m/z intensity on the y-axis (Figure 10). The INCOS DS introduced a new era in the comparison of a spectrum of an unknown substance with those contained in a mass spectral database. The INCOS library search algorithm became the basis for most commercial DSs used with current instrumentation. INCOS was sold to Finnigan Corporation in the late 1970s. Finnigan quickly adapted the system for use with its line of TQ mass spectrometers. The INCOS DS gave Finnigan a significant advantage in its second generation of GC/MS instrumentation – the 4000 series.

The INCOS DS remained an exclusive of the Data General minicomputer long after many manufacturers had shifted DS developments to the IBM PC-type computer. This unusual longevity is rumored to have resulted from a settlement between Data General and Finnigan over the fact that the INCOS’ unique disk-operating system, IDOS, was an infringement of copyrights held by Data General on disk-operating systems.

Teknivent was another company that joined System Industries/Riber and INCOS in competition for the after-market DS business. Teknivent developed a series of DSs that were based first on various minicomputers and then on the IBM-type microcomputers (PCs). They were one of the first companies to introduce a GC/MS DS on the PC using the IBM PCXT ca. 1983. Teknivent was the only instrument company to use the IBM OS2 operating system, which allowed for control of multiple gas chromatograph/mass spectrometer systems from a single computer. A significant number of these DSs were sold through the late 1980s and early 1990s as replacements for minicomputer systems used with the Riber R10-10, Finnigan 3000 and 4000, and INCOS 50 series of GC/MS instrumentation as well as many of the Hewlett-Packard instruments that used UNIX and Pascal-based DSs. This St Louis, MO-based company ceased doing business around 1996, and its assets were acquired by ProLab Resources (Madison, WI), a company that had been functioning as a third-party software developer for GC/MS data analysis systems.

Although none of these original third-party DS manufacturers exist today (with the exception of Teknivent within ProLab Resources), the concept of after-market DSs is still very strong. Among the companies at the end of the second millennium, there is one that produces a system primarily for sector-based instruments – MSS in Manchester, UK. MSS also has a system for quadrupole instruments. Los Gatos Circuits (LGC, San Jose, CA) markets a DS for some models of TQ instruments that is produced by SysNet Corporation (Scotts Valley, CA). In addition, Shrader Analytical (Detroit, MI) has produced a system that is OEM to JEOL USA and sold as an after-market system for sector-based instruments.

Over the next few years, following the introduction of Finnigan’s first instrument, the field of GC/MS grew at an exponential rate largely fueled by a very active market in environmental chemistry. The Finnigan Model 1015/System 150 was the first commercial GC/MS DS and was introduced at the Fall ACS meeting in New York City in 1969. A short time later, Hewlett-Packard introduced an instrument also based on the TQ mass spectrometer, which helped to legitimize the TQ technique for organic MS. Although the growth has been nothing short of spectacular for the past 30 years, the start was slow with Finnigan selling only one Model 1015/System 150 in the 18 months after the New York introduction.

Hewlett-Packard and Finnigan dominated the GC/MS market, largely owing to the simplicity of operation of the TQ and the continued advancement of the DS. The LKB 9000, which had dominated the GC/MS market especially in biotechnology, in the last half of the 1960s fell into rather quick obscurity owing to the lack of a computerized DS. The major European and Japanese mass spectrometer manufacturers of the early 1970s concentrated on magnetic-sector mass spectrometers that had GCs as inlets. These efforts were never very successful because of the higher cost of the sector instruments, and insufficient emphasis was placed on the DS. The only other serious attempt at a magnetic-sector-based GC/MS system was made by DuPont with an instrument using a fixed-field magnet and a variable accelerating voltage. DuPont had acquired the mass spectrometer pioneer CEC from Bell & Howell in a last attempt to make the company competitive in the GC/MS marketplace, but it failed, largely owing to problems of source arcing at the high voltages required (in excess of 12,500 V) to look at ions below m/z 43.6

Hewlett-Packard and Finnigan continued to emphasize the DS as being as significant as the mass spectrometer; however, Hewlett-Packard began to look at the technique...
as one for the chromatographer rather than the mass spectrometrist. This approach led to the development of the benchtop GC-MS, which has dominated the market since 1982 with the introduction of the HP 5970. This benchtop GC-MS was followed by the introduction of an IBM PC-based DS for the Finnigan benchtop ITD™ 700 in 1984. Hewlett-Packard introduced the PC-based DS for the 597X family of instruments (5970, 5971, 5972, and 5973) in 1989. Currently, Hewlett-Packard has more GC/MS units in service than all other types of mass spectrometers combined, and the TQ m/z analyzer has long ago replaced the magnetic-sector m/z analyzer as the mass spectrometer of choice for GC/MS.

After Finnigan and Hewlett-Packard became dominant in the field of GC/MS, other companies have developed popular products such as the Shimadzu OP 5050 and the Perkin-Elmer Qmass and Turbomass, both based on the transmission quadrupole. Finnigan introduced the ITD™ 700 in 1984 based on the QIT m/z analyzer. Through a technology purchase and an initial OEM agreement, Varian advanced Finnigan’s internal ionization QIT to the point of being a dominant player in today’s GC/MS market. More recently, LECO Corporation has introduced a rapid acquisition GC/MS system based on time-of-flight mass spectrometry (TOFMS) technology developed at Michigan State University that will acquire 1000 spectra per second over an m/z range of 1000 and will allow for greatly reduced analysis times. Micromass/Waters introduced a GC/TOFMS system at the 1999 Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy (Orlando, FL) that has the conventional EI and CI sources in addition to an EI source. This instrument has the capability of exact mass measurements. The magnetic-sector-based mass spectrometer has returned to the GC/MS field with a reverse-geometry, double-focusing, exact-mass-analyzer as the analyzer for one of its adaptations: microES or nanoES), they enter the mass spectrometer as solvated ions. Whereas in GC/MS, samples are introduced into the mass spectrometer as analytes in the gas phase from either a packed or capillary column (or one of the several iterations of the capillary column), where they are ionized. In LC/MS, analytes can enter the mass spectrometer in solution from an analytical (usually 4.6 mm ID) or capillary (≤2 mm ID) LC column via flow injection, or through direct infusion of a liquid that flows because of a pump [e.g. microelectrospray (nanoES)] or due to electro-osmotic flow [e.g. nanoelectrospray (nanoES)], or as components from capillary electrochromatography or capillary electrophoresis. In some cases, these analytes are ionized in the mass spectrometer, and in others (e.g. ES or one of its adaptations: microES or nanoES), they enter the mass spectrometer as solvated ions. Whereas in GC/MS the chromatographic mobile phase is an inert single component (usually helium or hydrogen) and the only concern is its contribution to the pressure inside the ion source, the mobile phase in LC/MS is often a complicated mixture of solvents and nonvolatile substances, some of which may be present to react purposefully with the analytes to improve chromatographic separations but interfere with the formation of gas-phase ions. All of this makes LC/MS a much more complex issue than ionization of gas-phase analytes.

**Figure 11** EI of methane followed by fragmentation of the molecular ion. The methane molecular and fragment ions then react with molecules of methane (ion/molecule reactions) to produce various types of methane reagent ions used to bring about the CI of an analyte.

**2.4 Liquid Chromatography/Mass Spectrometry – A Slow Start – But a Fastcomer in the Backstretch**

LC/MS is a more-encompassing term than GC/MS. In GC/MS, samples are introduced into the mass spectrometer as analytes in the gas phase from either a packed or capillary column (or one of the several iterations of the capillary column), where they are ionized. In LC/MS, analytes can enter the mass spectrometer in solution from an analytical (usually 4.6 mm ID) or capillary (≤2 mm ID) LC column via flow injection, or through direct infusion of a liquid that flows because of a pump [e.g. microelectrospray (microES)] or due to electro-osmotic flow [e.g. nanoelectrospray (nanoES)], or as components from capillary electrochromatography or capillary electrophoresis. In some cases, these analytes are ionized in the mass spectrometer, and in others (e.g. ES or one of its adaptations: microES or nanoES), they enter the mass spectrometer as solvated ions. Whereas in GC/MS the chromatographic mobile phase is an inert single component (usually helium or hydrogen) and the only concern is its contribution to the pressure inside the ion source, the mobile phase in LC/MS is often a complicated mixture of solvents and nonvolatile substances, some of which may be present to react purposefully with the analytes to improve chromatographic separations but interfere with the formation of gas-phase ions. All of this makes LC/MS a much more complex issue than ionization of gas-phase analytes.
Charge transfer (the reagent ion, missing an e\textsuperscript{−}, takes an e\textsuperscript{−} from the analyte)
\[ \text{CH}_4^+ \text{RH} \rightarrow \text{RH}^+ + \text{CH}_4 \text{ M}^{++} \]

Proton transfer (most common when the analyte molecule has a higher proton affinity than the reagent gas. The analyte takes H\textsuperscript{+} from the reagent ion)
\[ \text{CH}_3^+ \text{RH} \rightarrow \text{RH}_2^+ + \text{CH}_4 \text{ [M + 1]}^+ \]
\[ \text{C}_2\text{H}_5^+ \text{RH} \rightarrow \text{RH}_2^+ + \text{C}_2\text{H}_4 \text{ [M + 1]}^+ \]

Hydride abstraction (the reagent ion has a high hydride affinity, the ability to remove a H\textsuperscript{−} from the analyte molecule)
\[ \text{CF}_3^+ \text{RH} \rightarrow \text{R}^+ + \text{CF}_3\text{H} \text{ [M − 1]}^+ \]
\[ \text{C}_2\text{H}_5^+ \text{RH} \rightarrow \text{R}^+ + \text{C}_2\text{H}_4 \text{ [M − 1]}^+ \]

Collision-stabilized complexes (occurs when the PA of the analyte and reagent gas are comparable. The reagent ion becomes attached to the analyte. When methane is used, this series, [M + 1]\textsuperscript{+}, [M + 29]\textsuperscript{+}, and [M + 41]\textsuperscript{+}, is a very good confirmation of molecular weight)
\[ \text{C}_2\text{H}_5^+ \text{RH} \rightarrow (\text{C}_2\text{H}_5 : \text{RH})^+ \text{ [M + 29]}^+ \]
\[ \text{C}_3\text{H}_5^+ \text{RH} \rightarrow (\text{C}_3\text{H}_5 : \text{RH})^+ \text{ [M + 41]}^+ \]

Figure 12 Types of ion/molecule reactions that result from positive-ion CI.

GC/MS was an established technology within the first 5 years after the introduction of the first commercial instrument – the Finnigan Model 1015/System 150 in 1969. By the end of the 1970s, GC/MS dominated the field of MS, and the TQ mass spectrometer was an accepted technology. LC/MS has been a different story. The interface posed a more difficult problem. Dealing with a gas load of 20–30 mL min\textsuperscript{−1} (typical carrier gas flow rates for packed columns used with early GC/MS instruction) was very different from 550 mL min\textsuperscript{−1} of gas (at atmospheric pressure and room temperature) produced from a flow of 1 mL min\textsuperscript{−1} of acetonitrile eluting from an LC column. It was also important to the early developers of LC/MS that the spectra be produced by EI. The EI spectra requirement meant that the analyte had to be in the gas phase at some point; therefore, the technique would have been limited to analytes that were not in an ionic form in the LC eluate.

The earliest attempts were made by Patrick Arpino and Fred McLafferty with a technique called ‘direct liquid introduction’ (DLI)\textsuperscript{71} (Figure 13). These attempts were carried out by using EI and the relatively new technique of CI. Attempts were made to use the volatilized mobile phase of the LC process as a reagent for a CI process.

Following attempts at the DLI (which were never very successful from a commercial standpoint) came the moving-belt interface (Figure 14), pioneered by William McFadden at Finnigan Corporation.\textsuperscript{72} This technique did not offer a great deal more usable data than DLI; however, it was commercially much more successful because the ion-source pumping requirements were much less. The limitation of a somewhat volatile analyte remained.

A technological success for an interface between a LC and a mass spectrometer was the original work on API done by Evan Horning’s group at the Baylor College of Medicine (Houston, TX) in the mid-1970s.\textsuperscript{73} This technique involved the formation of ions of the intact analyte through a CI process that was cried out at atmospheric pressure. At the time of this development, not much acceptance was forthcoming because only molecular weight information was generated. The customary fragmentation data used for structure elucidations was missing. Horning called this technique ‘API’. API is the term now applied to the two techniques involved with
getting ions into the gas phase at atmospheric pressure: APCI and ES.

The APCI technique requires the analyte to be volatile enough to allow for a gas-phase ion–molecule reaction to take place, which means that the analyte cannot be in the ionic phase in the LC eluate. This volatility requirement, coupled with the fact that for the most part only molecular weight information resulted, led to an initial limited use. The technique required a lot of pumping that added to the cost and complexity of commercial instrumentation. APCI did not become popular until after the development of the triple-quadrupole mass spectrometer, which allowed for MS/MS of these ions representing the intact molecule, thereby producing structural information about the analyte. APCI also became a good companion for ES because both were atmospheric techniques and used similar interfaces to the mass spectrometer.

Today, APCI and ES dominate LC/MS instrumentation. The only other LC/MS technique that was commercially viable at the end of the 20th century was the particle beam interface developed by Ross Willoughby and Robert Browner in the mid-1980s. This technique allows for acquisition of EI and CI mass spectra of analytes in the gas phase after a partial desolvation using a heated drying gas and momentum separator. Clumps of moist analyte molecules are propelled onto a heated plate located in the ion source of the mass spectrometer. These moist clumps striking the heated plate result in the volatilization of the analyte molecules, allowing for their subsequent ionization in the gas phase. Although this technique can yield more structural information about the analyte, it has much poorer sensitivity than ES or APCI and has the limitation of the volatile requirement for the analyte.

During the mid-1980s, two different independent approaches were made to LC/MS that used the DI technique FAB by Y. Ito and Richard Caprioli. These techniques were called ‘frit-flow FAB’ and ‘continuous-flow FAB’, respectively. Again, these were labor-intensive techniques and were far from allowing for routine analyses. However, at the time, this was the only technique that allowed for the analysis of nonvolatile thermally labile LC analytes such as polysaccharides, peptides, and oligonucleotides. These iterations of FAB have been replaced by ES.

Another abortive attempt at LC/MS was a technique called ‘thermospray’. Thermospray was pioneered by Marvin Vestal, currently at PE Biosystems and at VesTech and the University of Houston at the time this technique was developed, in the early 1980s. The original form of this technique (filament-on) was similar to the DLI. Later, a technique was serendipitously developed called ‘filament-off’ for the analytes that were in an ionic form in the LC eluate when ion current was observed after a failure of the filament. Even though the thermospray technique was also labor intensive and fraught with many difficulties, it had a reasonable commercial success in that investigators were desperate for tools to analyze substances separated by LC.

Beginning in the mid-to-late 1980s with publications by John Fenn and Jack Henion, the technique of ES started to evolve. After Fenn, Mathias Mann, and C.K. Meng published an article entitled ‘Protons or Proteins – A Beam’s Beam’ in 1988, ES and its companion technique of APCI underwent a logarithmic growth in improvement, numbers of applications, and advancements in the commercial instrumentation. ES went from being a research-laboratory curiosity to one of the most widely used tools in biotechnology.

Techniques such as continuous-flow fast atom bombardment (CF-FAB), currently being developed, will take LC/MS into expanded areas of use in organic chemistry and biotechnology.

2.5 Desorption/Ionization

DI is the term applied to the processes by which mass spectrometrists ‘... make elephants fly’. DI is a technique in which ions are formed in other than the gas phase, and the ions are then desorbed from the matrix where they are formed into the gas phase. Currently, the two most widely used and popular DI techniques are MALDI and ES. However, although not as widely employed, the techniques of FI and FD and also FAB are still in use. A new TOF-based GC/MS system was introduced by Micromass at the 1999 Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy (Orlando, FL), which had an FI source available as an option. It is still common to find abstracts in almost every issue (once every 2 weeks) of CA Selects Plus MS (a publication of the Chemical Abstracts...
Service of the ACS) on the use of FAB or CF-FAB in LC/MS applications.

Another important DI technique that is still widely used is DCI. This probe technique is especially suitable for use with TQ mass spectrometers. Vinca Promavcich, organic analytical facilities manager in the Department of Chemistry, Columbia University, says, “When these organic chemistry students bring samples (‘pure’ or mixtures for GC/MS analysis), the first thing I do is try them [the samples] with DCI. If I do not get usable spectra, then I will not take the chance of ruining a GC column or contaminating the ion source by trying the analysis of something that is probably a crystallized inorganic salt rather than the suspected reaction product.”

2.5.1 Field Desorption and Field Ionization

The first DI technique to be seriously considered in MS was FD. FD is an ionization technique by which analyte ions are desorbed from the surface of one of the two electrodes used to produce an electrical field. This technique was the first to allow the determination of the mass of analytes that were nonvolatile or thermally labile. FD uses specially prepared sample emitters that allow for the production of protonated molecules (MH⁺). Because single-charge ions are produced, the mass limitations at the time of the development were determined by the maximum m/z value of the mass spectrometer. Formation of ions via an electrical field had its origin with field-ion microscopy developed in 1951 by E.W. Müller in Germany. The first developments involving FD were by R. Gomer and M.G. Ingrahm.⁸³,⁸⁴

The technique of FI of gas-phase analytes was an outgrowth of the development and study of FD. FI is a technique, rivaling CI, that results in a high abundance of intact adduct ions of the analyte molecule ([M + H]⁺, [M + Na]⁺, etc.). The ions are captured by a dense matrix of needles of graphite on its surfaces. The process of preparing the filaments and introducing the sample without disturbing this delicate forest of needles is an art form in and of itself. Although FD was used to a large extent as the only technique for nonvolatile thermally labile analytes from its development in the 1960s, it was largely replaced with other less- tedious techniques such as FAB, DCI, and now MALDI and ES.

2.5.2 Plasma Desorption (²⁵²Cf Desorption/Ionization)

The next DI technique to be developed was that pioneered by Ronald D. Macfarlane at Texas A&M. For the most part, the technique of ²⁵²Cf DI (Cf DI) [or plasma desorption (PD)] remained a laboratory curiosity through its useful life. The dependence of PD on TOFMS was not sufficient to prevent the last US manufacturer of these instruments (CVC Corporation) from discontinuing their manufacture in the late 1970s. There was a single commercial attempt at a PD instrument in the 1980s by Bio-Ion in Uppsala, Sweden. The instrument was later marketed by Kratos Analytical, UK. Bio-Ion was later acquired by Applied Biosystems (now PE Biosystems).

The primary reason for the lack of popularity of Cf DI was the radioactive nature of the ionization source, which presented a significant safety and disposal problem for a number of laboratories.

PD was first reported in 1974 with results obtained from the nonvolatile compound sodium acetate. This report predicted the use of PD for larger nonvolatile molecules such as biopolymers.⁸⁵ Two years later, Macfarlane’s group reported the analysis of a peptide with a molecular weight of 1881 Da.⁸⁶

PD is accomplished by putting the analyte sample on one side of a nickel or aluminized Mylar™ plate. On the other side of the plate is a 10µCi ²⁵²Cf source. Each fission event results in two products of nearly equal mass, each having energies of 80–120 MeV propelled in opposite directions. One triggers the start of the detector and the other rips through the sample holder to desorb intact adduct ions of the analyte molecule ([M + H]⁺, [M + Na]⁺, etc.). The ions are captured by the ion optics of a specially designed TOFMS instrument and are accelerated into its flight tube. Mass spectra are accumulated over a period of several hours depending on the signal strength of each event and the required signal-to-background for the analysis.

Macfarlane also developed the method of ES for the deposition of the sample on the PD sample holder.⁸⁷ Peter Roepstorff (Odense University, Denmark) became an outspoken proponent of the technique in support of Bio-Ion.⁸⁸

The DI technique that showed mass spectra could be obtained from large peptides and proteins as well as other biologically significant substances such as
mass spectrometry was the genesis of bioanalytical MS. This DI technique is no longer in use, even in university research laboratories.

2.5.3 Fast Atom Bombardment

In an effort to use MS for the analysis of proteins, investigators attempted to get results by layering the purified protein onto a metal surface and then used a SIMS technique (see section 2.7.3) to desorb ions from the surface of this open-face sandwich. This was not very effective because the energy absorbed by the sample often resulted in sample decomposition. When secondary ions were produced using lower-energy bombarding ions to avoid damage to the top layer of the analyte and prolong the secondary ion current, the analytical ion current was significantly reduced resulting in poor detection limits. Also, the SIMS technique resulted in an ion current of a very short duration, which also affected the detection limit.

In a further attempt to obtain better results from the ‘sputtering’ mass spectral ionization techniques, Mickey (Michael) Barber in the Department of Chemistry at the University of Manchester Institute of Science and Technology in the mid-1970s began to look at the possibility of using accelerated atoms to bombard the sample as opposed to ions. The decision to use atoms as opposed to ions was born out of the desire to use a double-focusing mass spectrometer that required ion acceleration of \( \sim 8 \text{kV} \). This technique was effective but, for the targeted organic analytes, suffered from the same short duration of ion current that had been observed with SIMS. When Barber’s group undertook this research, they had set the goal of developing a new ion source that met the following criteria: (1) produces ions at room temperature, thereby eliminating the necessity for volatilizing the analyte prior to ionization; (2) the ionization process should result in both the abundance of molecular ions to allow for molecular weight determination and fragment ions that can be used to deduce the analyte’s structure; (3) the mass spectrum resulting from this ionization process should have a sufficient lifetime to allow for techniques such as metastable ion detection, which can be time-consuming in a double-focusing mass spectrometer; (4) the detection limit should be such that structural information can be obtained from as little as 1 \( \mu \text{g} \) of analyte; and (5) the ionization technique should have the potential for easily and reproducibly generating mass spectra of analytes that have proved problematic or impossible by other types of ionization.

After half a decade of research and based on curious observations of sample contaminants by pumping fluids (e.g., Apiezon oils, Santovac 5, and Convalex 10) and glass–glass vacuum sealants such as siloxane stopcock greases, a way to prolong the ion current was found by mixing the analyte with a low-vapor-pressure viscous solvent. The first material found to be satisfactory for this technique was glycerine (glycerol) used to obtain the mass spectrum of a small peptide (methionine enkephalin, Figure 15).

The genesis of FAB is well chronicled in an Analytical Chemistry A-pages article that appeared in 1982. FAB was easily adaptable to existing TO and double-focusing mass spectrometers although the best results were obtained using the sector-based instruments. FAB met all of Barber’s objectives for a new ionization technique and was readily adopted by the MS community. A Boolean search of MEDLINE (http://www.infotrieve.com/freemedline/) for ‘FAB’ yielded 6 papers in 1981, 69 in the period 1981–1984, and over 325 in the period 1985–1989. This last number is far from the total number of publications that appeared using this powerful technique during that period. FAB also found immediate applications in the technique of MS/MS using both TO and reverse-geometry double-focusing instruments (see section 2.6). FAB differed from either FD or PD in that it was easy to prepare sample, easy to use, and spectra could be obtained in a reasonable period rather than the hours or days required for PD. As soon as fragmentation spectra were being obtained from peptides, schemes for their interpretation were developed. FAB allowed for the more
realistic characterization of microorganisms by MS that was pioneered by Catherine Fenselau at the University of Maryland, Baltimore County.\textsuperscript{94}

As a variation of FAB, the technique of liquid secondary ion mass spectrometry (LSIMS) was developed. Instead of the beam of neutral atoms being fired at the mixture of analyte and carrier, a beam of ions is used. For the most part, the same results are obtained. The LSIMS technique imparts more energy to the analyte. As described above under LC/MS, FAB proved to be a useful technique with dynamic separations as well as one that allowed for the analysis of purified samples. FAB was still in use at the end of the 20th century; however, it has largely been replaced by MALDI and ES.

2.5.4 Desorption Chemical Ionization

As MS developed, techniques evolved to introduce sample in all three physical states of matter (gas, liquid, and solids). Some solids had sufficient volatility that results could be obtained by putting the material on the end of a probe placing the probe tip in the mass spectrometer’s ion source and heating the probe to produce a vapor that was ionized. In some cases, this proved to produce better quality spectra than could be obtained by volatilizing the sample outside of the ion source.\textsuperscript{95} In 1973, Fred McLafferty introduced the technique of placing a sample on a probe and heating it while subjecting it to an ion plasma produced in a CI source by showing a spectrum of a nonderivatized peptide (VAAF) with a large protonated molecule \((M + H)^+\) peak and other peaks that were used to determine the sequence.\textsuperscript{96} This variation of the technique used to introduce samples on a direct-insertion probe (or solids probe) has been called ‘direct CI’, ‘in-beam’, ‘direct exposure’, and ‘desorption CI’.\textsuperscript{97} The last has been the accepted name for a number of years.

Desorption electron ionization (DEI) has also been used. The probe used for DCI and DEI is called a ‘direct-exposure probe’. The direct-exposure probe is distinguished from the solids probe in that the sample is placed on the outer surface of the probe, whereas the sample is placed in a hollow cavity at the tip of the solids probe. This hollow cavity is often similar to a short (5–10 mm long) melting-point capillary tube.

Today’s direct-exposure probes are constructed with a filament that can be rapidly heated. The physical shape, material of construction, and treatment of these filaments all contribute to the results obtained. A sample is dissolved in an appropriate volatile solvent, a drop of the solantoin is placed on the filament so that the filament is fully and evenly coated, and the solvent is then evaporated (Figure 16). The filament on the end of the probe is passed through the vacuum lock into the ion source of the mass spectrometer. A current is passed through the filament, which results in rapid heating. DCI takes place when a CI plasma is present, and DEI results when only a beam of electrons is used for ionization.

The exact mechanism of this ionization has never been clearly explained. Evidence has been shown that indicates the intact analyte is desorbed from the surface of the filament, and ionization takes place in the gas phase.\textsuperscript{98} This evidence supported an approach that used rapid heating. However, the difference in ion current obtained with different reagent gases indicated that the ionization was taking place on the surface of the filament, and the ions were then desorbed into the gas phase.\textsuperscript{99} DCI is especially applicable to use with TQ mass spectrometers. It is unclear whether it was a combination of filament physical design and manufacturing material or factors pertaining to ion-source potentials, but results obtained using TQ instruments appeared to be significantly better than those obtained with sector-based instruments. DCI will produce mass spectra from nonderivatized sugars and other organic compounds that are thermally labile.

DCI produced spectra for many compounds that had been unsuccessfully ionized by FD. One of the more significant examples was the mass spectrum of brevetoxin B obtained by Koji Nakanishi at Columbia University in the mid-1980s on a Nermag R10-10 TQ mass spectrometer (Figure 17).\textsuperscript{100} The Nermag R10-10’s DCI probe used the coiled filaments shown in Figure 16. These filaments were constructed of a thoriated tungsten. This instrument, using this particular design, produced some of the best DCI spectra obtained on a commercial instrument. This particular technology is still commercially available through ThermoQuest’s Automass Multi combination GC/LC/MS system.

DCI was developed and matured in the same time frame as FAB. Both techniques were amenable for
compounds that were thermally labile and/or nonvolatile. DCI has been a very good technique for use with TQ mass spectrometers, which are more limited in their maximum m/z detectability than double-focusing instruments. FAB is the preferred technique for proteins and peptides, whereas DCI works nicely with 1–5 saccharide sugars and coordination complexes.

2.5.5 Matrix-assisted Laser Desorption/Ionization

MALDI is a technique by which an analyte is mixed with an energy-absorbing matrix. Analytes are usually of high molecular weight (>2 kDa), and the matrix is usually of a much lower molecular weight (~0.5 kDa or less). Each is separately introduced into a shallow well on a flat plate in solution, where the two components are mixed through the natural mixing of the solutions. The solvent is evaporated leaving a solid mixture of matrix and analyte. This mixture is then subjected to a blast from a laser [both IR and UV lasers have been used]. The matrix molecules absorb the energy of the laser shot (Figure 18a–c). The energized matrix molecules are then responsible for the formation of protonated molecules that are passed into the gas phase, partly due to the ablation of the sample caused by the impact of the laser. This technique was found to produce ions of intact molecules that were mostly single-charge ions, but there is also the possibility of double- and triple-charge ions. The mass spectrum can also contain peaks representing dimers and trimers of the analyte (not very common). MALDI was developed by two German scientists (Franz Hillenkamp and Michael Karas) working at the Institute für medizinische Physik und Biophysik, Universität Münster (Münster, Germany).\(^{[101]}\)

MALDI allows the detection of ions representing intact proteins and other biopolymers that had masses in the tens to hundreds of kilodalton range. The fact that MS could be used to determine the mass of such substances was the good news. The bad news was that most of the mass spectrometers currently in use at the time MALDI was developed could not be used to separate ions of such high mass-to-charge ratios as experienced in this type of analysis. The upper m/z limit of the sector-based mass spectrometers was often only around 2000 Da.
spectrometer is a function of the maximum magnetic field that could be produced and still be stable. The instruments that rely on RF (TQ and QIT mass spectrometers) are limited by the maximum amplitude that could be obtained for a given frequency before the wave will break up. The only mass spectrometer that was not affected by one of these limits of the physics involved with the ion separation is the TOF mass spectrometer. Unfortunately, TOFMS instruments had fallen into the realm of an historical curiosity by the time MALDI was developed. Just a few years earlier, the only manufacturer of TOFMS instruments had stopped their production. There was little or no interest on the part of research laboratories in the USA or Europe in developments of TOF. There was still a fairly active interest in TOFMS in what was then the Soviet Union (now Russia and some of the countries just to the west of Russia). The power and advantages of MALDI resulted in reassurances in TOFMS to the point that many new applications have been developed for this MS technique. At the end of the 20th century, TOFMS was not only important to MALDI MS but also found uses in inductively coupled plasma mass spectrometer (ICP-MS), GC/MS, ES and APCI LC/MS, and SIMS used in surface analyses.

FAB was the gleaming new technology that dominated MS throughout the 1980s. MALDI has been the technique of the 1990s and, along with ES, has largely replaced FAB even though Analytical Chemistry did publish a review of commercially available FAB instrumentation as late as October 1997. (102)

2.5.6 Electrospray

Unlike all the previous types of DI, ES is unique in that the mass spectrometer is not necessarily involved in the ionization process. All the other DI techniques involve the formation of ions in the condensed phase by some process in the ion source of the mass spectrometer followed by the desorption of these ions into the gas phase. In ES, the analyte enters the mass spectrometer in solution already in an ionic state. Although the exact mechanism of ES is still widely debated, (20) it is generally agreed that solvated ions in charged droplets are desolvated in the interface of the mass spectrometer, which is why some people do not call the process ES ‘ionization’. If ionization is a process of forming ions, then ES should not be called ionization; if ionization is a process by which ions are put into the gas phase, then ES is an ionization process.

The technique of ES, popularized in the last decade of the 20th century, has a long history that goes back to the 1930s.

2.6 Types of Mass (m/z) Analyzers

The part of the mass spectrometer used to separate gas-phase ions according to their m/z values is the mass analyzer. Mass analyzer is the traditional terminology. This term was satisfactory when used with instruments that existed before the 1990s because almost all encountered ions that had only a single charge. The term mass and m/z were used interchangeably, which led to labeling the x-axis of spectra with terms that were units of mass. After the popularization of ES, the multiple-charge ion became more commonplace; and, while always problematic, labeling the x-axis of a mass spectrum with unit-of-mass terms became a potential for conveying incorrect information.

As an example, the DS accompanying an LC/MS instrument featuring an ES interface introduced in 1996 had the x-axis of all the spectral displays labeled ‘amu’. Amu was not only an incorrect term (owing to its replacement with the symbol u in 1962) for mass, but the use of any term or symbol for a unit of mass on an axis that should have been labeled m/z, especially for spectra that contained peaks primarily representing multiple-charge ions, was also unconscionable.

Mass (m/z) analyzers can be divided into two broad categories: (1) those that in some way isolate ions of individual m/z values from a beam–beam-type instruments; and (2) those that store ions of all m/z values and detect ions through some process of single m/z isolation – traps. Magnetic-sector, double-focusing, TOF, and QIT MS spectrometers are beam-type instruments. QIT (both external and internal ionization variations) and ICR mass spectrometers are traps.

2.6.1 Magnetic-sector Mass Spectrometer

Magnetic-sector mass spectrometers use only a magnetic field to separate ions according to their m/z values (Figure 19). These instruments are referred to as single-focusing mass spectrometers. They are capable of separating ions that differ in one m/z unit over a range from 1 to ~700 m/z. These types of instruments have been used as residual gas analyzers (RGAs) for analysis of elements, as isotope-ratio mass spectrometers, and as general analytical mass spectrometers for organic compounds. As one of the first mass spectrometers designed specifically for use in GC/MS, the LKB 9000 was based on a single-focusing magnetic sector. Owing to the inability of these instruments to acquire sequential mass spectra rapidly because of the hysteresis inherent in electromagnets and the complexity of the electronics resulting in a high initial cost and difficulty of operation, these types of instruments quickly dropped from commercial popularity for use in hyphenated techniques such as GC/MS when the TQ GC-MS was introduced in the late 1960s.

The explosion of new mass spectrometer manufacturers that came about after World War II resulted in several popular models of single-focusing magnetic-sector instruments. These instruments included the AEI (name
of Metropolitan Vickers parent company, Associated Electrical Industries, after 1960; see below) MS-2, MS-3 and MS-5; the MAT-Atlas CH-4 and CH-5; and the CEC 21-103C and 21-130.

2.6.2 Double-focusing Mass Spectrometer

Double-focusing mass spectrometers use a magnetic field to select ions based on their \( m/z \) values and an electric field to select ions based on their energy. These instruments became the workhorse of MS from the 1930s through the end of the 1970s. These instruments are capable of separating ions with very small differences in \( m/z \) values allowing for the determination of the elemental composition of the ion based on these millimass measurements.

CEC was the first commercial manufacturer of double-focusing mass spectrometers beginning before World War II. After World War II, manufacturers and instrument designs sprung up in the UK (Metropolitan Vickers delivered its first instrument in 1946 in Manchester, UK); Germany [Mes und Analysen-Technik (MAT) founded in 1947 in Bremen, Germany, as a subsidiary of Atlas-Werke AG]; and Japan (JEOL and Hitachi having existed as analytical instrument manufacturers before the war). At the beginning of the 21st century, a spinoff from Met Vickers (VG Analytical, now Micromass, Manchester, UK, a wholly owned subsidiary of Waters Corporation), JEOL, and the current owner of MAT (ThermoQuest) are the only commercial manufacturers of double-focusing mass spectrometers. Of these three manufacturers, JEOL is the only company that continues to have this type of mass spectrometer as its only mass spectrometer offering.

Names of the developers of the ion-optics systems used in double-focusing mass spectrometers are often associated with the instrument [e.g. Neir–Johnson (Figure 20), Mattauch–Herzog (Figure 21), and Bainbridge–Jordan].

The technique of MS/MS was developed as a result of forced metastable \( ^{103} \) ion formation between the two sectors of the double-focusing mass spectrometer. By placing (Figure 22) the magnetic sector as the first field following the ion source (reverse geometry) as opposed to the traditional configuration of having the electric sector as the first field (forward geometry), routine MS/MS experiments could be carried out. This MS/MS technique remained popular until the development of the triple-quadrupole mass spectrometer (two TQ \( m/z \) analyzers separated by a third quadrupole operated in the RF-only mode used as a collision cell). MS/MS in the double-focusing mass spectrometer is an important selling feature of the JEOL LCMate and GCMate at the beginning of the third millennium. Although the TQ instruments remain dominant in MS/MS, the QIT is gaining in importance to this technique.

Many of the often-cited scientists \((^{6,10})\) in MS had a great deal to do with the development of double-focusing
instruments. They were the people who were involved with applications development and ion optics. However, a number of other factors that took place behind the scenes were just as important. One of these factors includes the development of microprocessor electronics, which reduced the need for fine-tuning of the instrument by highly skilled operators. Another important factor was the development of the laminated magnet in the 1970s. This development helped to overcome the hysteresis problems with magnets that were the limiting factor in scan speed. The double-focusing mass spectrometer became a commercially viable instrument after World War II largely because of the advances in vacuum technology that grew out the use of the mass spectrometer as a preparative tool in the development of the atomic bomb.2

2.6.3 Time-of-flight Mass Spectrometer

The next gas-phase ion-separation technique in MS was involved with the development of the time-of-flight mass spectrometer (TOF-MS). Ions of different \( m/z \) values accelerated from a region such as an ion source into an evacuated tube will have different velocities, and therefore these ions will reach the end of this evacuated region at different times. By separating the times at which ion current is observed at a detector placed at the end of this evacuated region, it is possible to obtain a mass spectrum. Ions of the lowest \( m/z \) will reach the detector first (Figure 23).

The earliest report of experimentation with the concept of TOF for gas-phase ion separation was by William R. Smythe (US scientist) and Josef Heinvich Elizabeth Mattauch (Austrian physicist) in 1932. According to an account by Robert W. Kiser in his book *Introduction to Mass Spectrometry and its Applications*, the history of the early development of the TOF-MS involved a number of people.

While at the University of Pennsylvania (Philadelphia, PA), W.E. Stephens reported on the concept of the TOF-MS in an abstract appearing in the American Physical Society’s program in 1946. Some 7 years later, Stephens published a paper with M.M. Wolff with the same title as Stephens’s 1946 abstract, ‘A Pulsed Mass Spectrometer with Time Dispersion’, which described the instrument they had built based on the TOF principle. The seminal paper on TOFMS, ‘TOF Mass Spectrometer with Improved Resolution’, was published in 1955 by two researchers working for Bendix Aviation Corporation Research Laboratories in Detroit, MI. This paper provides a detailed treatment of ion focusing in the TOF-MS. The Wiley–McLaren paper was considered to be of enough importance that it was republished in the Journal of Mass Spectrometry in 1997.

According to a citation in Robert Cotter’s book *TOFMS: Instrumentation and Applications in Biological Research* (ACS, Washington, DC, 1997), “... it was estimated that in 1962, one-third of the mass spectrometers in use in the United States were TOF instruments”. In his 1965 book, Kiser states that the bulk of the US market had been provided by CEC (approximately 700 instruments). Considering these two statements, it is possible to believe that by the mid-1960s, only 10 years after Wiley and McLaren’s paper, there were over 300 TOF mass spectrometers in use in the USA, and most of them had been manufactured by what later became known as the Bendix Corporation. In the mid-1960s, the future for the TOF-MS looked very bright. However, this was before the commercialization of the TOF mass spectrometer.

The Bendix Corporation was sold to Consolidated Vacuum Corporation, later known as CVC Products (Rochester, NY). Sale of TOF mass spectrometers declined to the level that CVC discontinued their manufacture sometime in the late 1970s to early 1980s. The popularity of the TOF-MS went through a period
of rapid decline until the development of MALDI by Franz Hillenkamp and Michael Karas in the late 1980s. In the decade that followed, the renewed interest in the TOF-MS resulted in an explosion of new developments, which included greatly improved resolving power, very rapid acquisition of data, and new ionization techniques such as Aviv Amirav’s supersonic beams. Beginning with the introduction of commercial MALDI TOF mass spectrometers in the mid-1990s followed by the explosion of TOF instrumentation in LC/MS, the TOF-MS has re-established itself as a significant factor in the industry (Figure 24). LECO Corporation (St. Joseph, MI) is a newcomer to MS through the acquisition of a GC/MS TOF system (Pegasus II) and an LC/MS TOF system (Jaguar) where both instruments represent new paradigms in their respective hyphenated techniques. Micromass and PE Biosystems both have an LC/MS product using TOF technology and an MS/MS hybrid instrument (TQ TOF). These instruments, which became widely used at the end of the 20th century, are just the genesis of the new TOF-MS. Within the next decade, the TOF-MS could supersede the TQ as the most used instrument in MS.

2.6.4 Transmission-quadrupole Mass Spectrometer

The TQ mass spectrometer uses a quadrupole field produced by a combination of DC and RF voltages that are applied to four conducting surfaces that have a hyperbolic cross-section. The first TQ mass spectrometers used four opposing round rods arranged parallel to one another to create this field. The TQ is often referred to as a ‘mass filter’ because it can be set to allow an ion of a single $m/z$ value to pass through it while removing ions of all other $m/z$ values from an ion beam. Quadrupole technology (which includes the TQ and monopole mass filters and the QIT) was first explored by Wolfgang Paul and colleagues at the University of Bonn (Bonn, Germany) in the early 1950s. The initial paper on the quadrupole technology was followed by a detailed description of the theory. Paul shared half of the 1989 Nobel Prize in Physics with the German-born American physicist Hans Georg Dehmelt, the developer of the Penning (magnetic) trap, ‘for the development of ion-trap techniques’. The quadrupole ion trap was an outgrowth of his study of quadrupole fields. The monopole was commercialized in the 1960s by General Electric Corporation but never became very popular. The seminal reference on the quadrupole technology is Peter Dawson’s *Quadrupole MS and its Applications* (Elsevier: Amsterdam, 1976; reprinted by the American Institute of Physics, Woodbury, NY, 1995).

The TQ mass spectrometer was very well suited for use with the emerging field of GC/MS. This $m/z$ analyzer requires a much lower accelerating voltage EI and CI ion source than the sector instruments. It was smaller in physical size and much more suitable to rapid scanning and electronic control than the sector instruments. The TQ has a practical capability of producing unit-resolution spectra over an $m/z$ range from 0 to ~4000.

The well-established mass spectrometer manufacturers of the time (which also included VG Analytical, a company that began some years after the others) were all committed to the magnetic-sector and double-focusing technology. Two companies new to MS (Finnigan Corporation, Sunnyvale, CA, now part of ThermoQuest Corporation, Austin, TX; and the California Instrument Division of Hewlett-Packard Corporation, Palo Alto, CA, now part of the HP spinoff Agilent Technologies, Palo Alto, CA) were the first to introduce GC/MS instrumentation based on the TQ mass spectrometer and are equally responsible for success of this type of mass spectrometer. At the end of the 20th century, there were more TQ mass spectrometers in use than all other types of mass spectrometers combined. In 1999, more GC/MS and LC/MS instruments using a TQ $m/z$ analyzer were purchased than all other types of $m/z$ analyzers combined.

An important note about the TQ that might have fallen from the pages of history if not for an article by Robert F. Finnigan on the history of TQ is that while Paul and his colleagues pursued this technology, Richard Post at the University of California Lawrence Berkeley Laboratory carried out independent research in the 1950s on the same technology. Post did not publish or apply for patents on his findings. Other than information contained in his personal notebooks, the only record of his work is a University of California Radiation Laboratory Report (UCRL 2209) published in 1953.

Robert Finnigan (whose background was electrical engineering) actually began his quest for a TQ GC-MS at a process instrument and controls group that
he and a physicist colleague, P.M. Mike Utte (from Lawrence Livermore National Laboratory and then Stanford Research Institute, SRI), founded for Electronic Associates Inc. (EAI, Long Branch, NJ), an analog computer company. From the founding of this group within EAI in 1964 until 1967, Finnigan and his colleagues produced over 500 RGA instruments using the TQ. TQ mass spectrometers continue to have extensive use as RGAs. This RGA experience with EAI gave Finnigan Corporation a solid background in TQ technology. Along with several others from EAI and the then general manager of Varian’s chromatography business, Varian Aerograph, T.Z. Chu started Finnigan Corporation in January 1967. The goal of this company was to produce an easy-to-use, low-cost GC-MS based on the TQ mass spectrometer.

The first Finnigan GC/MS instruments sold for about $35,000, which was far less than any of the sector-based instruments. The TQ mass spectrometer was particularly suited to the newly emerging digital minicomputers. Finnigan Corporation, through a personal relation between Bob Finnigan and Ed Zschau (Stanford Business School Professor and early Silicon Valley entrepreneur) formed a relationship with Zschau’s new company, System Industries, by which SI commercialized a DS based on the Digital Equipment Corporation’s PDP-8 computer that had been in the Genetics Department at Stanford’s Medical School. Although the GC-MS was a low-priced item, adding the $50,000 for the DS produced a rather pricey item. Finnigan Corporation introduced the first GC-MS DS at the Fall ACS meeting in New York in 1969. This instrument was delivered to Evan Horning’s group at the Baylor College of Medicine (Houston, TX).

By the early 1970s, computerized GC/MS systems based on the TQ mass spectrometer were established analytical instruments. However, the $150,000 price for these instruments ($450,000 in the mid-1990s) prevented their wide use. Hewlett-Packard’s (HP) efforts in the early days of TQ GC/MS have not been as well chronicled as those of Finnigan Corporation. HP’s early efforts did not result in the same initial impact as Finnigan’s, but the subsequent efforts of HP led to the affordability of the TQ-based GC-MS DS. Other companies played a key role with respect to the TQ mass spectrometer in the decade of GC/MS (1970s) and the decade of MS/MS (1980s). These companies are SCIEX (Toronto, Canada, now selling its instruments through PE Biosystems, Foster City, CA), Extranuclear Laboratories (Pittsburgh, PA, later known as Extrel, now operating as ABB Extrel and no longer providing analytical instrument systems), Riber/RiberMAG/Nermag (a French company still in France and owned by ThermoQuest), and VG Micromass. The only double-focusing instrument manufacturer at the time Finnigan and HP introduced their first instruments that were able to embrace successfully the TQ technology was VG Analytical (now operating as Micromass).

In addition to the continued manufacture of TQ m/z analyzers for use in GC/MS and LC/MS by ThermoQuest and Agilent Technologies, high-quality analytical instruments used for these purposes are also available from Waters/Micromass, Shimadzu, Perkin-Elmer Analytical Instruments (a division of EG&G), PE Biosystems/SCIEX, Hitachi, and others. The TQ is also used in RGAs and ICP mass spectrometers.

2.6.5 Quadrupole Ion-trap Mass Spectrometer

The QIT mass spectrometer was born out of the same Paul research that produced the transmission quadrupole; however, the QIT did not become a commercially viable instrument until the mid-1980s. The QIT uses a three-dimensional quadrupole field to store ions of multiple m/z values as opposed to filtering out ions of all m/z values except those of a selected value from an ion beam. The QIT consists of two end-caps electrically isolated on either side of a ring electrode placed between the two end-caps (Figure 25). This three-dimensional device has a hyperbolic cross-section.

The primary premise of any mass spectrometer has always been that the ions had to be separated in an area of low pressure. When ions were introduced into or formed inside the QIT maintained at traditional mass spectrometer operating pressures of $10^{-6} - 10^{-10}$ Torr, it

![Figure 25](image-url)
was found that while storage was very efficient, separating ions that differed by no more than an integer \( m/z \) value was not possible. Serendipitously, George Stafford and co-workers at Finnigan Corporation (San Jose, CA) found that by using a light buffer such as helium to maintain the trap at about \( 10^{-3} \) Torr produced excellent unit resolution and improved sensitivity.\(^{115}\) This late-1982 discovery coupled with Stafford’s earlier announcement of the mass-selective instability scan allowed the commercialization of the \( \text{I}^2\text{QIT} \) instrument. Ray March, in the preface to *Particle Aspects of Ion Trap Mass Spectrometry, Vol. I: Fundamentals of Ion Trap Mass Spectrometry* (CRC, Boca Raton, FL, 1995), states that Stafford’s mass-selective instability scan is as significant as Paul’s work.

Stafford’s initial breakthroughs of buffer gas use and the mass-selective scan mode led Finnigan to announce the first commercial GC-MS based on a QIT – the ITD\(^{800} \) 700 (an \( \text{I}^2\text{QIT} \) device) – at the 1983 Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy (Atlantic City, NJ). The plan had been to begin shipping instruments by mid-1983; however, shipments did not begin until December 1984. One of the problems that delayed shipment of the ITD\(^{800} \) 700 was mis-mass assignment for the molecular ion peak of some analytes that were unrelated to space-charge effects or ion/molecule reactions (both related to pressure, explained below). This mis-mass assignment was compound (ion) specific. The final solution resulted in the ‘stretched’ trap. This stretched trap did not result in a homogeneous quadrupole field, which had previously been thought to be a requirement for proper ion separation,\(^{116}\) but was found as the only way to overcome this particular problem.

Even with many of the initial problems of bringing the \( \text{I}^2\text{QIT} \) GC-MS to market overcome in an intensive development cycle as described by John Syka\(^{115}\) (ThermoQuest, San Jose, CA), the instrument met with a mixed reaction regarding its usefulness as a GC/MS instrument by those who received these first units. Because packed GC columns were predominant among GC users (especially in the USA), the interface between the GC and the mass spectrometer was a device that split the GC eluate with one part in 10 going to the mass spectrometer and the remainder going to atmosphere as a discard (the open-split interface). This split arrangement often resulted in a higher than desired amount of analyte in the trap. The amount of analyte was dependent on its initial concentration in the GC eluate. Ionization took place in the trap for a fixed time period (settable by the operator). If the amount of analyte was too high and a larger number of ions than could be stored in separated orbitals were produced, a space-charge mass spectrum would result with clusters of peaks on either side of the nominal \( m/z \) value peaks. There was no way to prevent this space-charge effect because the partial pressure of the analyte could not be controlled nor the ionization varied as a function of analyte partial pressure.

Unlike the beam-type mass spectrometers (sector, TOF, and TQ), which detected ions a few microseconds after their formation, the QIT stored ions for long periods (during the ionization time) in an area with analyte molecules. Depending on the ions formed by the analyte, this could lead to ion/molecule reactions that produced mass spectra that exhibited much higher than normal \([M+1]^+\) peaks. This phenomenon (sometimes referred to as self-CI) is analyte dependent. The most dramatic example of self-CI can be observed in the analysis of 2-octane (MW 128). This compound can produce a mass spectrum with essentially a single peak at \( m/z \) 129, which represents the protonated molecule. These ion–molecule reactions between an analyte and fragments of its molecular ions can easily be avoided in modern QIT instruments.

The problems with space-charge effects and self-CI resulted in a lot of criticism directed toward the ITD\(^{800} \) 700. On the other hand, the good sensitivity of this instrument was unprecedented. Users found detection limits lower than they had ever believed possible. Further development by Finnigan led to a modification in data acquisition that produced a variable ionization period based on the partial pressure of analyte. This development went a long way toward correcting the space-charge problems. Another significant factor about this particular fix was that it involved only a software modification. No additional hardware was required. Existing users could have their space-charge problems addressed with a software upgrade. Finnigan had entered into an OEM agreement with Perkin-Elmer Corporation (Norwalk, CT) whereby Perkin-Elmer sold the ITD\(^{800} \) 700 to customers that were not disclosed to Finnigan. While Finnigan upgraded all of its customers to the next generation of the \( \text{I}^2\text{QIT} \) software (ITD\(^{800} \) 800), unfortunately, Perkin-Elmer did not, thereby resulting in many dissatisfied initial ion-trap users.

In 1989, Finnigan sold rights to use their ion-trap patents to Varian Associates’ Analytical Instrument Division (now Varian Corporation, Palo Alto, CA). This assignment of rights to Varian was followed by the introduction of the third-generation \( \text{I}^2\text{QIT} \) GC/MS system (Varian’s Saturn and Finnigan’s ITS40). By this time, the capillary GC column had replaced the packed column, and a number of significant hardware and software advancements had been made by Finnigan. One of the most significant was the ability to apply an RF voltage, which was at half the frequency of that applied to the ring electrode, to the two end-caps. This feature known as axial modulation greatly increased the storage capability of the trap, further reducing space-charge problems.\(^{117}\)
The I\(^2\)QIT went on to demonstrate other advantages such as low-pressure CI (reagent gas partial pressure of 10\(^{-5}\) Torr compared with 0.1–1 Torr in beam-type instruments), MS/MS in time and MS\(^n\), and selected ion storage. Some 16 years after the introduction of the first commercial QIT mass spectrometer, a GC/MS instrument using external ionization is available from ThermoQuest; an internal ionization GC is still produced as several models by Varian worldwide, and Hitachi manufactures and sells an internal ionization GC-MS in Japan; ThermoQuest has two models of a second-generation API (ES and APCI) LC-MS; and Hitachi and BrukerDALTONICS (in a joint marketing agreement with Agilent Technologies) produce an ES QIT LC-MS. Because of the multiple iterations of ion isolation followed by CAD, the QIT is of particular interest to LC/MS. For this same reason and the extreme good sensitivity, QIT technology is also very popular with GC/MS users. The QIT GC-MS is the instrument of choice for the analysis of air pollutants. The best reference for understanding the physics of the QIT is *Quadrupole Storage MS* by R.E. March and R.J. Hughes (Wiley, New York, 1989).

### 2.6.6 Ion Cyclotron Resonance and Fourier Transform Ion Cyclotron Resonance Mass Spectrometer

The ICR mass spectrometer is the other type of ion trap – magnetic as opposed to quadrupole. Whereas the quadrupole ion trap is referred to by the name of its original developer (the Paul trap), the ICR is called the Penning trap, a name given by its developer, Hans G. Dehmelt.\(^{(118)}\) Dehmelt’s work with the development of the ICR, which began in 1955 at the University of Washington (Seattle, WA), led to his sharing half of the 1989 Nobel Prize in Physics with Wolfgang Paul. The ICR is a combination of the magnetron and the Penning ion source. Unlike the omegatron that uses a fixed-field magnet, the magnetron/Penning mass spectrometer uses a variable-field magnet.

The Fourier transform ion cyclotron resonance mass spectrometer (FTICR-MS) was developed by Allen Marshall and Melvin B. Comisarow when they applied Fourier transform algorithms to the mass separation technique of ICR in 1974.\(^{(119)}\) The application of the Fourier transforms to detect ions separated by the ICR technique improved it to the point that the technique became of significant value to analytical chemistry. This instrument is capable of extremes in high-resolving power (Figure 26) and has proved to be of great value in ES LC/MS where the number of charges on an ion can easily be determined by counting the number of isotope peaks within one \(m/z\) unit.

The FTICR-MS requires the use of a superconducting magnet, which, depending on the magnet’s field strength, can add significantly to the cost. The higher the field

![Figure 26](image-url)
strength, the higher is the \( m/z \) range of the instrument. These instruments also require a very skilled operator and need a lot of maintenance. In a 1998 article, Alan Marshall stated, “... more than 235 [Fourier transform ion cyclotron resonance mass spectrometry (FTICRMS) instruments] installations by 1998”.  

In all likelihood, most of these instruments were installed within the past 5 years and are in use with ES interfaces for the analysis of proteins.

Over the 24 years since Marshall and Comisarow first published their findings, three companies commercially manufactured these instruments: Nicolet Instrument Corporation (Madison, WI), Bruker-Franzen Analytik GmbH (Bremen, Germany), and Ionspec Corporation (Irvine, CA). The lowest advertised price for an FTICR-MS in 1999 was approximately $350,000. Nicolet originally sold its patents and FTICR-MS business to Extrel (previously known as Extra Nuclear); Extrel was then acquired by Waters Corporation; Waters then sold the FTICR-MS business to Finnigan Corporation. Through all of these ownerships, instruments continued to be developed and manufactured in Madison, WI. In late 1998, Finnigan (ThermoQuest) closed all operations in Madison and began the development of a new FTICR-MS in their Bremen, Germany, factory. This new instrument has yet to be announced, leaving only Bruker and Ionspec as manufacturers of this system. The FTICR-MS began to gain a great deal of popularity for protein analyses by ES interfaces for the analysis of proteins.

In 1966, T.W. Shannon and McLafferty showed that by forcing decomposition of a stable ion, isomeric ions could be characterized. McLafferty cites several other examples in the ‘Introduction to Tandem Mass Spectrometry’ chapter in Tandem Mass Spectrometry, an early and important reference to this technology.

The acronym coined for the technique of bringing about a decomposition of a stable ion by a forced collision with neutral gas molecules was MS/MS. William F. Haddon defined the acronym as ‘MS/MS’ in a symposium organized by Michael L. Gross presented at the University of Nebraska (Lincoln, NE, November 3–5, 1976). The term was later defined by McLafferty and Frank M. Bockhoff as ‘mass separation/mass spectral characterization’ by analogy to GC/MS. However, MS/MS is the definition of MS/MS that is used today.

In his book Introduction to Mass Spectrometry, J. Throck Watson states, “From the stability standpoint there are roughly three types of ions produced in the [ion] source: (a) those that are stable for 100 \( \mu s \) or longer and thus reach the source intact, (b) those that decompose immediately (less than 10\(^{-7}\) s) after formation, and (c) those that decompose 1–100 \( \mu s \) after formation.” Watson goes on to define these three ions as stable, unstable, and metastable, respectively. These metastable ions had been obscured in the earliest mass spectrometers of Thomson and Aston. The peaks produced by metastable ions on the photographically recorded mass spectrum were different from those produced by stable ions in that they were more diffuse. Thomson said these peaks were a result of ‘secondary’ rays and Aston called these peaks ‘bands’ in the mass spectrum. The metastable ion \( m^* \) represents the precursor ion \( m_1 \) and its resulting fragment (product ion, \( m_2 \)) with the relation \( m^* = (m_2)^2/m_1 \). For a long time, these broad peaks in mass spectra interfered with the quantitation of individual compounds in hydrocarbon mixtures; therefore, the instruments were tuned to avoid their appearance. As time progressed, it became obvious that not only did these bands result from decomposition of ions labeled as metastable; but, most of the time, ion decomposition in a mass spectrometer resulted from high-energy collisions of stable ions with background gas molecules in the mass spectrometer, which led to Fred McLafferty coining the term ‘CAD’. (104) [Graham Cooks coined the term ‘collision-induced decomposition’ (CID) in his 1978 book Collision Spectroscopy (Plenum, New York). Today, the CID abbreviation is used for collision-induced dissociation. Both CAD and CID are correct and are used interchangeably.]

"The acronym coined for the technique of bringing about a decomposition of a stable ion by a forced collision with neutral gas molecules was MS/MS. William F. Haddon defined the acronym as ‘MS/MS’ in a symposium organized by Michael L. Gross presented at the University of Nebraska (Lincoln, NE, November 3–5, 1976). (122) The term was later defined by McLafferty and Frank M. Bockhoff as ‘mass separation/mass spectral characterization’ by analogy to GC/MS. However, MS/MS is the definition of MS/MS that is used today.

After the developments of CI and FD, it became obvious that in order to get structural information from low-energy ions representing the intact analyte molecule that were produced by soft ionization techniques, some method of ion fragmentation would be necessary. As the possibility of CAD became more of a reality, new instrumental methods would be required. Much of the early significance came out of the work by Graham Cooks and his colleagues at Purdue. The early work can be found in Collision Spectroscopy, (124) a 1978 book that Cooks edited, and his 1973 book Metastable Ions. (103) Cooks also published an Analytical Chemistry A-pages article in the January 1978 issue entitled ‘Direct Analysis of Mixtures by Mass Spectrometry’, which described the potential power of what would become known as MS/MS. (169) (Figure 27)

Two significant hardware developments were reported in the mid- to late-1970s that propelled the field of MS/MS: (1) the adaptation of conventional double-focusing mass spectrometers to have ions pass from an ion source into a magnetic sector, then through a collision cell, and finally through an electric sector, thus allowing for
the determination of the mass of the precursor ion and the product ion by Micky Barber and R.M. Elliot in 1964; and (2) the development of the tandem-quadrupole mass spectrometer (the triple quadrupole) by Rick Yost and Chris Enke at Michigan State University (East Lansing, MI) using technology originally described by D.C. McGilvery and J.D. Morrison at La Trobe University (Bundoora, Australia). See Note 3 at the end of the article.

The about-to-be explosion of MS/MS was exemplified at the 1980 Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy (Atlantic City, NJ) with the introduction of three triple-quadrupole instruments (Finnigan Corporation, Extranuclear Laboratories, Inc., and SCIEX, Inc. – the TAGA 6000), a reverse-geometry double-focusing instrument by VG Micromass, Ltd. – the ZAB-2F (Cheshire, UK), and a triple-sector (electric–magnetic–electric) instrument custom-built for Mike Gross at the University of Nebraska with a price tag of $400,000–600,000. Twenty years later, SCIEX (marketed through PE Biosystems), Finnigan (as part of ThermoQuest), and VG Micromass (with a triple-quadrupole instrument as opposed to its original reverse-geometry double-focusing instrument and as a subsidiary of waters) are all still strong producers of MS/MS instrumentation.

The 1980s was definitely the decade of the triple-quadrupole m/z analyzer. As the quadrupole ion trap developed as a mass spectrometer, its role in MS/MS was obvious. The QIT mass spectrometer began the era of tandem-in-time as opposed to tandem-in-space (Figure 28). The concept of tandem-in-time allows for multiple iterations of ion isolation and CAD fragmentation (MS'). Although the quadrupole has helped to advance the technique of MS/MS, it is not a replacement for tandem-in-space, which still has an important role in the area of common-neutral-loss analysis and common product-ion scanning (Figure 29). Neither of these types of analyses are amenable for use with the tandem-in-time technique.
2.7 Inorganic Mass Spectrometry

MS was originally used to determine the isotopes of the elements. It found some of its first applications in elemental analysis. The only preparative applications of MS have been in the area of purifying isotopes of elements. In recent years, MS has played a more publicized role in the analysis of organic compounds. However, like the solid analytical technique that it is, MS has advanced significantly in inorganic analyses. Surface analysis used to characterize papers used in laser printers and metal and composite skins of aircraft and materials put into outer space have advanced because of the continued development of SIMS. The ICP ion source for MS allows for the detection of trace elemental impurities in semiconductor manufacturing and the monitoring of inorganic pollutants in drinking and wastewaters.

2.7.1 Glow Discharge Mass Spectrometry

Glow discharge (GD) is the oldest ionization technique used in MS. John Aston gives a detailed account of his experiences with GD in the 1942 second edition of his book entitled Mass Spectra and Isotopes. This technique was soon replaced by the spark-source technique in MS. In his 1965 book, Robert Kiser states, “The gaseous discharge ion source is largely of historical interest...”. John Roboz gives it about the same amount of space in his 1968 book.

Although GD is best known as an ionization source for MS, it can be used in conjunction with other analytical techniques. GD has experienced a renaissance of interest in the last 20–30 years, largely due to the work of Willard W. Harrison at the University of Florida (Gainesville, FL). An Analytical Chemistry A-pages article by Harrison, ‘GD Techniques in Analytical Chemistry’, appeared in 1990 that described the use of GD with atomic absorption spectroscopy (AAS), atomic emission spectroscopy (AES), and atomic fluorescence spectroscopy (AFS) in addition to MS.

One of the advantages that GD has over the other popular technique used for the analysis of inorganic samples (ICP) is that direct sampling of solids can be accomplished by GD. ICP requires that samples be in solution and nebulized or introduced as very fine aerosols. These aerosols can be produced from laser ablation or electrothermal vaporization. However, these intermediate sample techniques add to the cost and complexity of the method.

Another significant difference in these two inorganic MS techniques is the difference in the source pressure. The GD source operates at pressures similar to those used with CI in GC/MS, whereas the ICP source is an API source. A brief comparison of the operational parameters of the two techniques is described by Harrison. This paper also includes additional references to other sources of comparison.

A search for articles in all ACS journals over the period 1996–1999 that contained ‘GD’ in their titles resulted in a list of 24. All but four of these were in Analytical Chemistry, and five were authored by Harrison. A similar search for articles containing ‘ICP’ resulted in a brief list of about a dozen articles related to MS. It does appear that GD as an ion source has had a higher degree of interest over the last few years; however, there are far more manufacturers of ICP mass spectrometers than there are of GD instruments. In his 1990 review of GD, Harrison stated (without comment on the type of analyzer used) that commercial instruments were available from Extrel and VG Micromass. In all likelihood, the Extrel instrument was a TQ m/z analyzer and the VG Micromass instrument was based on a double-focusing sector instrument. In his 1999 paper, he states, “Although most commercial GD MS instruments are coupled with double-focusing magnetic-sector units, the most recent developments in GD MS have been performed using quadrupole and TOF systems”.

Like ICP-MS, a common problem in glow discharge mass spectrometry (GD MS) is interferences from isobars of specific analytes due to polyatomic clusters of the analyte atoms and the analyte atoms with the inert gas (often Ar) used to create the plasma. A great deal of research has been conducted that has resulted in overcoming this problem in the ICP mass spectrometer, but has not been surmounted in the GD mass spectrometer. The ability to analyze solids is significant, but may not yield as much information or
the type of information that can be gained from SIMS. One of the reasons that ICP-MS dominates over GD MS is because much of the analytical MS involved with inorganic sample deals with analytes in solution.

2.7.2 Inductively Coupled Plasma Mass Spectrometry

In the ‘Introduction’ chapter to *ICP Spectrometry and its Applications*, Dr. Gordon Wilkinson, Editor (Sheffield Academic: Sheffield, UK; and CRC LLC, Boca Raton, FL, 1999), Stanley Greenfield and Michael Foulkes state that the first record of an ICP was made by J.J. Thomson in 1891. Like GD, ICP is applicable to AAS, AES, and AFS in addition to MS.

Unlike GD, ICP did not become a mass technique until the mid-1970s, which was partly due to the requirement that the ICP be produced at atmospheric pressure. ICP had to wait until problems with API MS could be resolved. In 1974, Alan A. Gary, University of Surrey (Guild, Surrey, UK) published the use of a plasma jet as the ion source for a TQ mass spectrometer. Gary continued to publish on this technique; however, in 1980 he took part in a feasibility study that changed his ion source to an ICP. The results of this study showed that elemental and isotopic compositions of solutions could be obtained with relatively little sample preparation. This study was done with Robert S. Houk, who is at the US Department of Energy Ames Laboratory and the Department of Chemistry, Iowa State University (Ames, IA). Houk continues to be one of the leading researchers in ICP-MS.

Shortly after the Houk/Gary paper appeared, commercial instruments began to be introduced. The last half of the 1990s saw a number of new instruments and several significant technology advances. The 1997 and 1999 first-place Analytical Instrument Industry (AII) Report (Dr Gordon Wilkinson, Editor) Editors’ and Writers’ Award for the top three new instruments introduced went to instruments with ICP-MS technology advancements. The 1997 award went to Micromass (Manchester, UK) for the Platform-ICP (a TQ ICP mass spectrometer that used ‘ICP-HEX-MS’ to eliminate interferences from argon isotopes and reduce the energy dispersion of ions). The 1999 award went to Perkin-Elmer (Wilton, CT) and MDS SCIEX (Concord, Ontario, Canada) for the ELAN 6100 DRC (dynamic reaction cell) ICP/MS system. The PE/SCIEX DRC addressed the same problems as Micromass’ ICP-HEX-MS, but used a different technology.

Another significant advancement for ICP-MS was the introduction of a benchtop instrument by Hewlett-Packard (now Agilent Technologies) in 1997 through a joint venture with a Japanese developer. This product has been very successful and has brought ICP-MS within reach of many laboratories. Since 1994, every Pittsburgh Conference has seen the introduction of one or two new ICP-MS instruments. The ICP-MS technology is interfaced to double-focusing magnetic-sector TQ and TOF mass spectrometers. LECO Corporation (St. Joseph, MI) and GBC Scientific Equipment Pty. Ltd. (Dandenong, Victoria, Australia) introduced TOF-based ICP-MS instruments at the 1998 Pittsburgh Conference (New Orleans, LA). ICP-MS appears to have a good future in inorganic MS analyses.

2.7.3 Secondary Ion Mass Spectrometry

SIMS was an early development in MS. The study of surfaces by ‘sputtering’, although not thoroughly understood, was reviewed by H.S.W. Massey and E.S.H. Burhop in 1952. They reported that in 1931 K.S. Woodcock at the Ryerson Physical Laboratory, University of Chicago (Chicago, IL), observed secondary-ion formation when a surface was bombarded with an ion beam. According to Charles M. Judson, Richard Herzog filed a German patent application for a SIMS instrument in 1942. In 1951, R.H. Plumlee reported on ion-sputtering techniques as being employed by RCA Laboratories (Princeton, NJ) for the analysis of solids in a symposium entitled ‘Mass Spectroscopy in Physics Research’ held September 6–9, 1951, at the NBS (now NIST). R.E. Honig, also an employee of RCA Laboratories, is credited with much of the early work that proved productive in this field.

SIMS involves the formation of ions on or near the surface by bombarding the sample with a beam of mass-selected ions. The resulting secondary ions are desorbed into the gas phase. This technique was used to study the impurities in material such as the aluminum used for airplane wings and germanium wafers used in early solid-state electrical devices. SIMS and its variants are widely used in the analysis and study of surfaces of all types of material—from papers used in laser printers, to microprocessor devices, to the wings of aircraft manufactured from many new polymeric composites.

As an interesting point, the abbreviation for SIMS is a pronounced acronym with an obvious ‘s’ at the end, whereas the abbreviation for the technique used in chromatography/MS, selected ion monitoring (SIM), should not be used as an acronym because of the potential for confusion of these two entirely different techniques. Unfortunately, because of its ease of use, many people say ‘... analyzed by SIM’ or ‘... a SIM analysis’ rather than using the proper form ‘... analyzed by S-I-M’ or ‘... an S-I-M analysis’. It is also proper to say each word when talking about either technique, but never use SIM as an acronym.

3 THE FUTURE OF MASS SPECTROMETRY

From its beginning with Thomson’s 1897 report of the discovery of the electron (using what is considered
by many as the first mass spectrometer – the parabola mass spectrograph) to the present day status, the mass spectrometer has been and continues to be probably the most widely used analytical instrument. In all likelihood, MS technology has had the greatest impact on society of any analytical technique. Its nearest rival, nuclear magnetic resonance (NMR) spectroscopy, while enjoying a wide degree of use, has not had the impact of MS. The commercialization of and advances in (1) MALDI and ES instruments for the analysis of nonvolatile and thermally labile organics, (2) SIMS used in the characterization of organic and inorganic surfaces, (3) the specialty uses of MS such as RGAs that are used in space helmets to monitor patient health and medication performance, and in semiconductor manufacturing, (4) IR MS, and (5) ICP-MS have made MS a common technique for all fields of science.

The first 50 years were dominated by the physicists and their quest for the understanding of the ion optics of the magnetic-based single- and double-focusing instruments. As a result of MS’s role in the development of the atomic bomb in World War II, the underlying principles of the sector-based mass spectrometer were well understood as we headed into the postwar years. The 1950s saw the embrace of the mass spectrometer by the organic chemist, the development of TOF technology, and the embryo of the quadrupole field by the physicist. The 1960s resulted in increased usage of MS by the organic chemist with the development of new ionization techniques such as CI and FD. The 1960s were also a period for the advances of MS instruments as RGAs and as a technique for the characterization of surfaces.

The 1970s were the decade of GC/MS and an entirely new paradigm for the analysis of complex mixtures of organic compounds. GC/MS led to new ways of looking at drinking and waste waters and drug metabolites, and for solving forensic puzzles, to name just a few of the new abilities. These analysis enhancements were possible because of the commercialization of the TOF, which radically changed the field of organic MS. Unfortunately, the 1970s also saw the beginning of the temporary decline of interest in the TOF mass spectrometer. The 1980s were the decade of MS/MS, and the 1990s were characterized by DI, which led to more developments in the area of LC/MS and the reemergence of the TOF mass spectrometer. During all three of these decades, uses of MS outside organic chemistry expanded, such as the popularity of ICP-MS using both the TOF and the double-focusing mass spectrometer.

As we move into the 21st century, MS takes on even more of a significance in science than it has had in the last decade. The MS literature is growing at a rapid rate with six English language journals devoted solely to the field.

The ACS Analytical Chemistry journal is at least 25% MS, and Elsevier’s Journal of Chromatography A and Journal of Chromatography B have as many articles related to the use of MS as they do to pure chromatographic techniques. By 1999, the extended abstracts, which comprised the proceedings of the ASMS annual meeting on MS and allied topics, had grown so large that it was no longer practical to publish a print edition. Therefore, after 38 years (the first time the meeting proceedings were published was 1961), ASMS discontinued publishing the proceedings of its meeting as a print issue and began sole distribution on CD-ROM.

Although yet to be established, it is possible that the next decade of MS will be the era of imaging. At the 1999 ASMS meeting (Dallas, TX), there were a number of reports on the use of MS to image the distributions of molecular-specific matter on the surfaces of materials such as contact lenses and in tissue slices from rat brain as well as polymeric surfaces that are used in composite aircraft wings.143

The advances that MS has made in (1) GC/MS and LC/MS, (2) surface analyses, inorganic analyses in environmental sciences and semiconductor manufacturing, to name only two, (3) residual gas analyses used in process monitoring and medicine, (4) detection of biological and chemical warfare agents, and (5) analyses of biopolymers with MALDI will continue at rates equal to those of the last three decades.

One thing is clear: In the first quarter of the 20th century, the inventions of Joe Thomson and John Aston in Manchester, UK, had as profound an effect on mankind as they did on the field of analytical chemistry.

4 EPILOG

It is important to remember that ‘What you know about a subject is not nearly as significant as knowing where to find out what you need to know about that subject’. To that end, Appendix 1 of this article is a listing of important Web sites in 1999 that will help you locate much of the information you may need about MS. Appendix 2 is a bibliography of books on MS that have been published through 1999. Appendix 3 comprises a series of tables with helpful information that will be valuable in the interpretation of mass spectra of organic substances.

The MS section of this Encyclopedia contains articles that deal directly with techniques. In addition, there are articles that pertain to specific areas of analyses and analytes that also contain information on the use of MS. All of these articles, along with the referenced books in Appendix 2, will be invaluable in a concentrated study of any aspect of this exciting field of science.

NOTE

1. MS measures the abundance of ions according to their mass-to-charge ratios. Therefore, the abscissa of a mass spectrum is generally labeled with the units of mass-to-charge, not mass. The exception to this is the labeling of the abscissa of a mass spectrum constructed from the charge deconvolution of data with a series of multiple-charge ions. The units of mass are either unified atomic mass units with the symbol ‘u’ or daltons with the symbol ‘Da’. The use of the symbol ‘amu’ for mass was discontinued in 1962.

The amu symbol for a unit of mass was used when the standard for mass was based on oxygen-16. Physicists reported mass based on the most abundant naturally occurring stable isotope of oxygen \(^{16}\text{O}\), established by Francis William Aston (1877–1945) in 1929 after his discovery that oxygen was composed of three different isotopes, two of which had a higher mass \((^{17}\text{O} \text{ and } ^{18}\text{O})\) than the most abundant isotope, which was assigned an exact mass of 16 \((1 \text{ amu} = 1/16 \text{ of the mass of } ^{16}\text{O})\). This definition was the basis of the physical atomic mass scale.
Chemists used amu to define a unit of mass as 1/16 the atomic weight (the average atomic mass) of oxygen [officially established in 1905 on the suggestion of the Belgian chemist Jean Servais Stas (1813–1891)]. This definition was the basis for the chemical atomic mass scale. The two scales differed by a factor of 1.000275 (physical > chemical).

An atomic weight is the weighted average of the masses of the naturally occurring stable isotopes of an element, and oxygen has three such isotopes. The atomic weight of oxygen was an absolute value of 16 by definition. The chemical atomic mass scale made the determination of the atomic weight of newly discovered elements easy by forming their oxides.

To eliminate the ambiguity between the physical and chemical standards, the standard of a single mass unit as 1/12 the most abundant naturally occurring stable isotope of carbon ($^{12}\text{C}$) was adopted in 1960 by the International Union of Physicists at Ottawa and in 1961 by the International Union of Chemists at Montreal. This standard is based on the independent recommendations of D.A. Olander and A.O. Nier in 1957. The symbol for the unified atomic mass unit was established as $u$, NOT $\mu$, which appears in the ASMS Guidelines and in the 4th edition of Interpretation of Mass Spectra (McLafferty, 1993).

Prior to the oxygen standards, the basis for atomic mass had been set ca. 1805 by John Dalton (1766–1844) as 1 for the lightest element, hydrogen. In 1815, the Swedish scientist Jöns Jacob Berzelius (1779–1848), set the atomic weight (relative atomic mass) of oxygen to 100 in his table of atomic masses; however, the Berzelius standard of mass was not accepted. Stas’s recommendation of setting the oxygen-16 standard allowed hydrogen to retain a mass close to 1, thereby keeping Dalton’s scale somewhat intact.

2. When formed, ASMS had three vice-presidents: Programs, Arrangements, and Data & Standards. The vice-president of Data & Standards was not elected by the ASMS membership, but was the elected ASTM E-14 Committee Chair. In 1974, the ASMS membership changed the role of the E-14 Committee Chair to that of a non-elected Director-at-Large. The role of the E-14 Committee Chair in ASMS changed again in 1974 when the ASMS membership voted to no longer have a member of the E-14 as an automatic member of the ASMS Board of Directors. This position was replaced by a third Member-at-Large for Measurements and Standards to be elected by the ASMS membership. From that time forward, reports of E-14 meetings no longer appeared in the proceedings of the annual ASMS Conference on MS and Allied Topics. This change was made by ASMS because the interest of the ASMS membership was far broader than that of the E-14 Committee, and the interest of the E-14 Committee represented a small fraction of the diverse MS interest of ASMS. The year after the E-14 Committee Chair’s removal from the ASMS Board of Directors, the ASTM abolished the official standing of the committee. Note: the above information is taken from reports of the annual meetings of ASMS from 1972 to 1998 as published in the Society’s annual proceedings.

3. As the MS/MS technique developed, the term ‘parent’ was used to describe the precursor ion. The use of this word resulted in some confusion because organic mass spectrometrists had traditionally called the molecular ion a ‘parent ion’. The product ion of a CAD was called the ‘daughter ion’. The parent–daughter terminology led one group to coin the term DADI (pronounced daddy) as an acronym for direct analysis of daughter ions. Today, this parent–daughter terminology is discouraged owing to its perceived offensive nature by some people. Therefore, the term DADI would no longer be appropriate.

APPENDIX 2: BIBLIOGRAPHY

(Reprinted with permission from O.D. Sparkman, Mass Spectrometry Desk Reference, Global View, Pittsburgh, PA, 2000)

Preparation of any such compilation is thwarted with the problem that by the time it reaches the intended audience, it will be out of date. Although this is the case with this current effort, the generation of this collection of book titles was, to some degree, inspired by two such collections that are found in books authored by Roboz in 1968 (reference 77) and Kiser in 1965 (reference 81). Both of these collections have proved to be invaluable in personal studies of MS. More recent collections of book titles in MS appeared in McLafferty and Tureček (Interpretation 6) and de Hoffman et al. (Introductory 8). Both of these collections, like the Roboz and Kiser collections, are dated, even though both were prepared in the 1990s.

The old adage, “You can’t judge a book by its cover!” is truer today than ever before. Although there has been a number of outstanding MS books that address the new technologies developed at the end of the twentieth century, the literature of MS has been cursed with a plethora of recently published titles that suffer from bad technical content, little or no competent copyediting, and/or amateurish and sloppy production. These problems are due to consolidations in the publishing industry resulting in fewer publishers, a perceived need for new titles to replace older ones and to provide information on a subject that has exploded in the last decade with new ionization techniques, and the lack of desire and ability of authors to research their subject and avoid the self-gratification of generating an avalanche of neologisms and technical errors. These types of problems were practically nonexistent in books on MS before 1990.

There is a well-written and organized general text on MS (Introductory 4) that suffers from a less than adequate production effort. In this particular book, there is a lack of consistency in the fonts used for the presentation of reaction schemes, figures are improperly imported from electronic submissions, and promised graphics on the inside cover are replaced with an easy-to-lose insert. This book is the singularly best modern text on MS partially because its thousands of journal references all have titles. It is a shame that the publisher did not make the effort to do a better job of the presentation. This is one of the reasons why you see more self-publishing (Introductory 2 and Technique 10).

Another book, produced by a major publisher, consistently uses the word “spectra” (the plural form) for the word “spectrum” (the singular form) (Technique 6). As a corollary to “you can’t judge a book by its cover”, “you can’t necessarily judge a book by its title”. A book was published with the title Understanding Mass Spectra – A Basic Approach (Technique 3) when the title Understanding Mass Spectra of Illicit Drugs would have been more reflective of the contents and the complex spectra presented. There are also problems with poorly translated foreign-language books such as one originally written in French and translated into English by a person whose native language was Chinese (Introductory 8); reviewed in J. Am. Soc. Mass Spectrom., 8, 1193–1194 (1997). Another problem with translated books is the delay in information. By the time one of these books reaches its intended audience, the information is dated. This is especially true with the rapid change that is taking place in LC/MS and MS and biotechnology.

Most of the books on MS come from the chemists who use the technique. Chemistry, unlike biochemistry and the biological sciences, has been slow to recognize the importance of the titles of journal articles in cited references. Most of the MS books published in the last 10 years (and nearly all those previously published) do not include titles with cited journal articles. That is why a special effort has been made to mark books that do use titles in cited journal articles in this bibliography. These books are noted with an asterisk (*).

This bibliography is presented in 11 segments. Book-related segments include Introductory, Reference, Technique-oriented, Interpretation, Historical Significance, Collections of Mass Spectra in Hardcopy; and Integrated Spectral Interpretation. Non-book-related segments include MS; GC/MS; and LC/MS Journals; Personal Computer MS Abstract Sources; Software; and Monographs. These segments are included because of their importance in finding information on MS.
There is no inclusion of specific articles from journals. Through the 1960s, such listings of journal articles were published in various forms—often by MS instrumentation manufacturers. However, since the development of comprehensive abstracts systems and their electronic availability, these printed listings no longer have much value. The Personal Computer MS Abstract Sources section is a guide to information on current journal articles.

There is no inclusion of Internet search engines such as Medline and Chemical Abstracts Service. Some of these search engines are found on the Important Worldwide Web URLs in Appendix 1.

There has been some duplication of book titles. For example, the Watson book (Introductory 4 and Interpretation 4) covers two areas of MS. This book is excellent for the interpretation of EI spectra, as well as an introductory book. All books are listed in chronological order by section.

Introductory Books

The Introductory Books section contains titles of introductory books on MS, GC, and LC. If you are going to own only one MS book, it should be Introduction to Mass Spectrometry, 3rd edition (Introductory 4). This is a comprehensive book that touches on all the current technology. This book provides an excellent understanding of EI fragmentation mechanisms (which is essential to the understanding of all fragmentation in MS); and, of great importance, all of the journal articles referenced have titles. Another important book in this section is Pushing Electrons: a Guide for Students of Organic Chemistry (Introductory 3). This is a student workbook and instills a good understanding of moving electrons within organic ions and molecules, which is also essential to the understanding of mass spectral fragmentation.

MS Fundamentals (Introductory 9) is not a book. It is a multimedia training tool consisting of a computer-based training program, video, and book. This entry is also listed in the Software section. To those who work with the TQ mass spectrometer, this multimedia presentation is indispensable. In order to get the most from any analytical instrument, you must have a thorough understanding of the technology. This multimedia presentation will result in that understanding, even in those who have little technical background.

The Introductory Books section has three Analytical Chemistry by Open Learning titles (Introductory 1, 10, and 16). These books are programmed-learning texts and are very good for self-study. Two of the entries in this section are video courses produced by the ACS (Introductory 15 and 19). Neither is recommended because the MS course is dated, and the GC course has too little emphasis on capillary columns.

Reviews issues of Acids (166). The ‘MS’ articles in the Fundamental and Proteins (624), and Oligonucleotides and Nucleic Low-intensity IR Radiation (18), Polymers (61), Peptides Techniques and Instrumentation (364), Isotope-ratio reviews (reference 5) had 1551 citations divided into the NIST) with 165 citations. The latest of these by John A. Hipple and Martin Shepherd (NBS, now This review began in 1949 with the article authored by John A. Hipple and Martin Shepherd (NBS, now with 165 citations. The latest of these reviews (reference 5) had 1551 citations divided into nine categories: Overview (5), Scope (173), Innovative Techniques and Instrumentation (364), Isotope-ratio MS (89), High-power Lasers in MS (51), Dissociation by Low-intensity IR Radiation (18), Polymers (61), Peptides and Proteins (624), and Oligonucleotides and Nucleic Acids (166). The ‘MS’ articles in the Fundamental Reviews issues of Analytical Chemistry have had Alma L. Burlingame as their primary author since 1972 with 14 consecutive articles.

An important aspect of using a mass spectrometer is ‘becoming one’ with the instrument. In order to accomplish this, you must have an in-depth working understanding of the instrument. The multimedia training program distributed by SAVANT, MS Fundamentals (Introductory 9 and Software 23), is an excellent aid to gaining this understanding of the TOF mass spectrometer. In addition, the Dawson book (Reference 63) is a seminal reference for the TOF and the QIT. The March and Hughes book (Reference 35) is the seminal reference for the QIT, and the Cotter book (Reference 12) is a likewise reference for the TOF mass spectrometer. Care must be taken with respect to the Cotter title because he has edited a book (Reference 20) that does not provide the detailed understanding of TOFMS. The same is true for the March and Hughes book because of a similar title edited by March and Todd (Reference 17). There is no good reference for the current technology of magnetic-sector mass spectrometers. The best material on understanding the fundamentals of a magnetic-sector and/or double-focusing instrument is the Roboz book (Reference 77). The best understanding of the workings of FTMS is found in an article, ‘Fourier Transform Ion Cyclotron Resonance Mass Spectrometry: A Primer’, authored by Allen Marshall et al. in Mass Spectrom. Rev., 17(1), 1–36 (1998).

Working with mass spectrometers often requires the derivatization of analytes to obtain the best results. This section has three good books that aid in this task (References 25, 53, and 78). In addition, there are two other books that do not primarily pertain to MS techniques: Basic Vacuum Practice from Varian (Reference 36) and The Mass Spec Handbook of Service by Manura (Reference 24).

It should be noted that several books of the 1960s and early 1970s have been reprinted in the past few years (References 63, 82, and 84) by the American Institute of Physics and the ASMS. This is not a new practice. Several titles were reprinted by a publisher other than the original publisher several years after the first printing. ASMS plans to reprint several other titles of both historical and technological significance over the next few years.

**Technique-oriented Books**

The books listed in this section pertain to specific techniques of MS and hyphenated chromatography/MS techniques. In some cases, the books are specific to certain types of analytes. Books of this type began to appear at the end of the 1960s (only one listing before 1970, Technique 91). Slightly more than half of these books (47 out of 90) have copyright dates in the last decade. Unfortunately, the last three or four years have seen a proliferation of very poorly written books with little or no copyediting and poor quality production.

One of the titles in this section (Technique 6), as well as one in the Interpretation Books section (Interpretation 3), is not of much merit. The JASMS reviews of both these books expressed an opinion that they would be more harmful to the reader than helpful [Technique 6: *J. Am. Soc. Mass Spectrom.*, 10, 364–367 (1999); Interpretation 3: *J. Am. Soc. Mass Spectrom.*, 9, 852–854 (1998)].

Many of the technique-oriented books are made obsolete by changing technology within a few years or months of their publication. A good example is the 1990 Yergey book (Technique 39) on LC/MS. Because of the massive advancements in technology that have taken place in the last 10 years, this book had little relevance to
the technique within 2 years of its publication. The book still has a great deal of value in that it provides good information on how to perform the chromatographic separations required in LC/MS, and it has an excellent set of journal-article references that contain titles. The problem of dated material can be especially significant with foreign-language books that are translated into English. Unfortunately, in some cases, publishers do not indicate that a book has been translated. It is only through careful research that the foreign-language routes of a book can be established. This is the case with Technique 2.

There are two books (Techniques 10 and 21) that are of particular value to the LC/MS and GC/MS practitioner, respectively. These two books have a great deal of practical information on the running of different types of analyses and are good aids in the decision-making process about how to proceed with a particular sample. The Willoughby book (Technique 10) has very useful information in deciding whether to use a contract laboratory or perform the analysis in-house. The Willoughby book was reviewed in *J. Am. Soc. Mass Spectrom.*, 10, 78–79 (1999), as was the Kitson book, *J. Am. Soc. Mass Spectrom.*, 9, 294–295 (1997). Care must be taken with respect to the unfortunate similarity between the titles of the Kitson book (Technique 21) and that of Technique 6.

Books that are edited works rather than having a single author generally do not get my approval. These edited editions often end up looking like a ‘camel’ (a horse designed by a committee). This is more true of books published in the last two decades than those published before that time. There is one notable exception in Technique 16 by Cole, reviewed in *J. Am. Soc. Mass Spectrom.*, 8, 1191–1192 (1997). This book is an excellent reference for those working in ES. The second edition of the Niessen book (Technique 5) is also a good reference for ES and also other LC/MS techniques. The single negative aspect of both of these books is that they do not include titles with journal citations.

There are two important references on environmental GC/MS that should be reviewed by anyone working in this area (Techniques 71 and 73). Although both of these books were written in the era of the packed column, the fundamentals of environmental analyses and the United States Environmental Protection Agency (EPA) tune criteria are covered in detail.

Another reference of the packed-column era is the McFadden book (Technique 86). This book, along with the Karasek book (Introductory 18), is very useful to those starting in GC/MS.

If you are using CI (either APCI or CI under the conditions normally encountered in GC/MS), you need the Harrison book (Technique 33). Unlike the Yinon book (Technique 27), this book is a second edition and is labeled as such.

In looking at new titles of technique-orientated books, care must be taken to know when the title is nothing more than the collection of a series of articles from a journal or a bound issue of a journal. The value of such books is often less than their extremely high selling price.

47. SCIEX, The API Book, SCIEX, Division of MDS Health Group, Mississauga, Ontario, 1990.
Interpretation Books

The seminal book for the interpretation of EI mass spectra is the McLafferty book (Interpretation 6). This book is extremely valuable, but may be too advanced for a beginner trying to self-teach. The beginner should try to start with either the McLafferty 2nd edition book (Interpretation 8) or the book by Shrades (Interpretation 1), both of which have been out of print for some time but can be found on the used-book Web sites.

The books by Budzikiewicz et al. (Interpretations 19, 23, and 24) were the first books written using mechanisms in organic reactions to describe the fragmentation of energetic ions produced by EI. The information in these books still has a great deal of relevance to the subject. All of the interpretation books listed in this section pertain primarily to odd-electron molecular ions formed by the EI process. The ions formed in LC/MS are predominately protonated molecules, which are even-electron ions. Even-electron ions fragment to produce other even-electron ions, which requires the breaking of more than one bond in the ion. Many of the neutral losses in even-electron ion fragmentation and odd-electron ion fragmentation are the same.

One important note on Interpretation 3: just as book titles can be similar (Techniques 6 and 22), people can have the same or similar names that can result in confusion. The author of Interpretation 3, Terrence A. Lee, a Department of Chemistry faculty member at Middle Tennessee State University in Murfreesboro, TN, should not be confused with Terry Lee, a noted researcher in MS of biological substances at the Beckman Research Institute, City of Hope/Division of Immunology in Duarte, CA.

Books of Historical Significance

* Note that historical references are in the Bibliography section of the Kiser book (Reference 81) and in the Information and Data chapter of the Roboz book (Reference 77).

Based on an 1886 paper [Berl. Ber., 39, 691 (1886)] by Eugene Goldstein (German physicist, 1850–1930) reporting the discovery of luminous rays emerging as straight lines from holes in a metal disc used as a cathode in a discharge tube (he called the rays Kanalstrahlen – canal rays) and the confirmation by Wilhelm Carl Werner Otto Fritz Franz Wien (German Nobel Laureate in Physics, 1911; 1864–1928) that Jean Baptiste Perrin’s (French physicist, 1872–1942) 1895 postulation that the rays were associated with positive charge by studying their deflection in electric and magnetic fields [Verh. Phys. Ges., 17, 1898 (1898); Ann. Phys., 65, 440 (1898); Ann. Phys. Leipzig, 8, 224 (1902)], the field of MS developed into a science between 1911 and 1925. This was due to the results of the experiments conducted by the three founding fathers of MS: Joseph John Thomson (English Nobel Laureate in Physics, 1906; 1856–1940); Francis William Aston (English Nobel Laureate in Chemistry, 1922; 1877–1945; Aston was an associate of Thomson in the Cavendish Laboratory in Manchester, England); and Arthur Jeffery Dempster (1886–1950, Canadian–American physics professor, University of Chicago).

In his 1968 book, Roboz (Reference 77) lists 20 selected papers for those wanting to learn the history of MS through original references (Chapter 14, page 490). Of these papers, five were authored by Aston, four by Dempster, and two by Thomson. Another three were authored by William R. Smythe (US scientist) and two by Kenneth Bainbridge (US physicist, 1904–1906, Director of the Trinity test – the first test explosion of the atomic bomb), who also were early pioneers in MS.

4. A series of books (Mass Spectrometry in Biochemistry and Medicine, Vols. 1 and 2, Advances in Mass Spectrometry in Biochemistry and Medicine, 1974, 1975; Mass Spectrometry in Drug Metabolism, 1976, Vols. 1, 2, 6, 7 and 8, Recent Developments in Mass Spectrometry in Biochemistry and Medicine, 1977–1980 and 1982), ed. A. Frigerio, published by Plenum and Elsevier, as the proceedings of a meeting organized by the Mario Negri Institute for Pharmacological Research in Milan, Italy.

**Collections of Mass Spectra in Hard Copy**

There have been many collections of mass spectra that have come and gone. In a 1985 monograph (*A Guide to, and Commentary on, the Published Collection and Literature of Mass Spectral Data*) published by VG Analytical (the UK MS company now known as Micromass/Waters), 33 separate collections were referenced. In 1974 and 1978, the ASMS published the 1st and 2nd editions of *A Guide to Collections of Mass Spectral Data*. These editions include 24 and 30 references, respectively. None of these collections has been lost. They have all been consolidated into either the NIST98 Mass Spectral Database or the Wiley Registry of Mass Spectral Data, or both. Some of these collections are not currently available in an electronic format, or the electronic format is only of abbreviated spectra that range from a minimum of 16 to a maximum of 50 mass spectral peaks (Collections 6). Hard-copy volumes are somewhat less valuable than electronic versions. The Cornu collection is even less valuable because it is a tabular listing of the 10 most intense peaks.

‡ Also available in electronic format.
† Out of print.

Mass Spectrometry, Gas Chromatography/Mass Spectrometry, and Liquid Chromatography/Mass Spectrometry Journals

Articles containing information on MS can be found in many different scientific journals in addition to those listed below. This is a listing of journals that are specific to MS (Journals 1, 2, 3, 4, 5, 6, 8, 9, 15, and 16), that pertain to a specific analytical technique (Journals 10 and 11), or that pertain to general chemistry (Journals 7, 12, 13, and 14). Some of the journals have complimentary subscriptions (Journals 12, 13, and 14), whereas other journals have annual subscription rates of thousands of dollars (Journals 1, 4, 6, 10, and 11). Some journals have reasonable society membership rates (Journals 2 and 7). The more expensive journals often have reasonable individual subscription prices (Journals 1 and 4).

In addition to review and research articles, most of these journals also provide software, books, and other items of interest to the mass spectrometrist. The exceptions are the proceedings of meetings (Journals 16 and 17) and list and/or abstract sources (Journals 8 and 9).

One of the interesting features of Journal of Mass Spectrometry (Journals 1) is a section entitled ‘Current Literature in MS’ that appears at the end of every issue. This is a bibliography of articles published over the past 6–8 weeks. It is divided into 11 major sections with the Biology/Biochemistry section subdivided into four additional categories. At the end of each volume, all the listings for the year are made available in a Microsoft® Access format that can be searched electronically.

7. Analytical Chemistry, American Chemical Society, Washington, DC.
8. CA SELECTS PLUS: Mass Spectrometry, American Chemical Society, Washington, DC.
12. American Laboratory, ISC, Shelton, CT.
13. LC/GC, Advanstar, Eugene, OR.
14. Spectroscopy, Advanstar, Eugene, OR.

Monographs

All the citations in this section are from VG Instruments/Micromass. All instrument manufacturers publish application notes; however, Micromass (and its preceding companies) is the only manufacturer that has published this type of general-topic monograph. These monographs are like review articles found in Mass Spectrometry Reviews or the Special Features section of the Journal of Mass Spectrometry. These monographs are not as well referenced as the articles in the two journals mentioned, but do provide a good overview of the subject. Such promotional material is of benefit to those wanting to get a quick understanding of a topic, and it is hoped that more of this type of material will be forthcoming.

Another example of the ready-reference-material approach to information dissemination is found in the Siuzdak book (Introductory 6). This book was written to provide a quick understanding of MS to biotechnology executives who have to make financial decisions about MS instrumentation and facilities.

**Personal Computer Mass Spectrometry Abstract Sources**

**Integrated Spectral Interpretation Books**

General integrated spectral interpretation books include information on the interpretation of proton NMR, IR, and mass spectra, as well as how to use UV data in conjunction with the previous three spectral techniques. Some books also include a section on $^{13}$C-NMR. These books are good for an overview of the subject, but do not provide the in-depth MS interpretational information.

In addition to the books listed below, the Mathieson book (Interpretation 22) is also an integrated book in that it includes separate sections on NMR and IR, in addition to the one on MS.

**Software**

There are several programs that are available as self-training. Those programs developed by the UK company
Cognitive Solutions (Software 10–13) are somewhat like English roast beef. They are intellectually nutritious; however, they fail to excite the experiential palate. Equivalent titles available from SAVANT (Software 14–22) will hold the user’s interest in a much more conductive manner for learning. Just as the MS Fundamentals program is a seminal tool in the development of the understanding of the TO mass spectrometer, Fundamentals of GC/MS is one of the better instrument-user software packages developed. This program was initially developed and sent out several times for review to a number of people who are involved in training on various aspects of GC/MS and in the development of training programs. The result is what is assured to become an award-winning effort.

All of the training programs from SAVANT and Cognitive Solutions were developed in Interactive ToolBook, a powerful tool for the development of training programs. All have tests built into the programs to allow the user to evaluate the results of the training.

The two volumes of SpectraBook are also based on the Interactive ToolBook platform. These two programs each contain data on 50 separate compounds: mass, proton NMR, 13C-NMR and IR spectra as well as the structure, molecular weight based on the atomic weights of each compound’s elements, physical properties, and several synonyms. Help files are provided to assist the user in developing desired interpretational skills. Another nice feature is the ability to display what properties result in specific spectral peaks. Placing the mouse pointed on a labeled mass spectral peak and holding down the left mouse button will result in a display of the mechanism(s) that produced the ion represented by that peak. Similar displays are provided for the other types of spectra.

It is unfortunate that the author of SpectraBook (programs copyrighted in 1990 and 1992) did not take more care to be correct in some of the presentations such as the use of \( m/z \) as the symbol for mass-to-charge (inappropriately written Mass to Charge on the abscissa of mass spectra) ratio instead of the \( m/e \) symbol, which was replaced in the 1970s. The indicated shift of pairs of electrons in the displayed mechanism for beta cleavage resulting from a gamma-hydrogen shift does not instill confidence in the accuracy of instruction.

The programs published by ChemSW (Software 1–9) are very well thought out and provide utilities that are not found in the data-system software for most, if not all, commercially available instruments. The titles of these programs are self-explanatory.

The two programs associated with the Wiley and NIST Mass Spectral Databases (Software 31 and 33) are widely available from a number of different sources. A number of GC/MS and LC/MS programs now provide the NIST Mass Spectral Search Program as the search routine used with their proprietary instrument software. Both of the programs are capable of reading most, if not all, commercially available instrument data formats.

- **a** The integer mass of the most abundant naturally occurring stable isotope of an element is the element’s nominal mass. The nominal mass of an ion is the sum of the integer masses of the elements in its empirical formula (e.g. C$_3$H$_6$O$^+$ has a nominal mass of 58).
- **b** The exact mass of the most abundant naturally occurring stable isotope of an element is the element’s monoisotopic mass. The monoisotopic mass of an ion is the sum of the monoisotopic masses of the elements in its empirical formula (e.g. C$_3$H$_6$O$^+$ has a monoisotopic mass of 58.0417).
- **c** Assume $X = 100%$; $X$ represents the relative intensity of the first peak in a cluster of peaks corresponding to isotopic variants of a given ion.
- **d** The factor is multiplied by the number ($n$) of atoms of the element present to determine the magnitude of the intensity contribution for a given isotope. For example, the contribution at $X + 1$ due to $^{15}$N for an ion containing three nitrogens would be $0.37n^2$ relative to 100 at $X$.
- **e** This may not always be the lowest mass naturally occurring stable isotope of the element, as is the case with the elements in this table. The lowest mass isotope of Hg is 196 and the nominal mass isotope is 202, seventh from the lowest mass isotope.
APPENDIX 3: MASS SPECTRAL INTERPRETATION DATA

EI fragmentation data are given in Tables 1 and 2, Figures 30 and 31, and Tables 3 and 4.

Proof of a Molecular Ion Peak – \( M^{+} \)

1. If a compound is known, the molecular ion has a mass-to-charge ratio (\( m/z \)) value equal to the sum of the atomic masses of the most abundant isotope of

Each element that comprises the molecule (assuming the ion is a single-charge ion).

2. The nominal molecular weight of a compound, or the \( m/z \) value for the molecular ion, is an even number for any compound containing only C, H, O, S, Si, P, and the halogens.

Fragment ions derived via homolytic, heterolytic, or sigma-bond cleavage from these molecular ions (even \( m/z \)) have an odd \( m/z \) value and an even number of electrons.

Fragment ions derived from these molecular ions (even \( m/z \)) via expulsion of neutral components (e.g. \( \text{H}_2\text{O}, \text{CO}, \text{ethylene} \)) have an even \( m/z \) value and an odd number of electrons.

Molecular ions of these compounds fragment via homolytic, heterolytic, or sigma-bond cleavage to produce ions of an even \( m/z \) value unless the nitrogen atom is lost with the neutral radical.
An even number of nitrogen atoms in a compound results in an even nominal molecular weight.

4. The molecular ion peak must be the highest m/z value of any significant (nonisotope or nonbackground) peak in the spectrum. Corollary: the highest m/z value peak observed in the mass spectrum need not represent a molecular ion.

5. The peak at the next lowest m/z value in the mass spectrum must not correspond to the loss of an impossible or improbable combination of atoms.

6. No fragment ion may contain a larger number of atoms of any particular element than the molecular ion.

Courses on the interpretation of mass spectra and techniques of MS are offered by the Continuing Education Department of the ACS: http://www.acs.org/education/profdevl/short.html.

This article provides a brief introduction to aspects of mass spectrometry (MS) that employ artificial intelligence.
1 INTRODUCTION

1.1 Definitions of Artificial Intelligence and Expert Systems

This article covers the application of AI and ESs as applied to the techniques of MS. ESs are methods or programs by which a fixed set of rules or data is used to control a system, analyze data, or generate a result. In contrast, AI is associated with the higher intellectual processes, such as the ability to reason, discover meanings, generalize, or learn. In relation to MS, AI is generally limited to cases wherein ANNs are employed to learn or discover new patterns or relationships between data. Reviews of AI and ESs are available.¹,²

1.2 Growth in Technology

The growth in MS has been spurred by improvements in software sophistication and computer capabilities. The ability of computing systems to both collect and analyze data has grown very rapidly since the 1970s. The most important improvements have been in calculation speed of the machines, their ability to store large amounts of data very quickly, and their size. These improvements have allowed processes such as multitasking during data acquisition, where the computer both collects data and controls the instrument operation, and automated spectral matching, where large volumes of data are quickly analyzed.

The improvements in computer technology have resulted in an increase in the performance and types of mass spectrometers available. For example, instruments with even the simplest types of mass analyzers are now computer controlled. This has dramatically increased the stability, reproducibility, and capabilities of these devices. It is now possible to perform a tandem mass spectrometry (MS/MS) experiment where the data collection parameters are changed on the millisecond timescale in response to the data collected.³ This allows a library search to be performed, possible match candidates to be experimentally tested, and a positive identification to be made, all during the elution of a chromatography peak.

The development of computers has also allowed the use of new types of MS. For example, the data generated by Fourier transform mass spectrometry (FTMS), pyrolysis, and electrospray MS would be very difficult if not impossible to collect and analyze without high speed computers.

1.3 Article Summary

This article includes sections on the history of computers in MS, MS data systems, biological applications, ANNs, and optimization techniques in MS. This article does not include a discussion of the use and development of libraries of electron impact ionization data or of peak deconvolution and component identification based on these libraries. Reviews of these topics are available.⁴,⁵

2 BRIEF HISTORY OF COMPUTERS IN MASS SPECTROMETRY

2.1 Introduction

Digital computers are now an indispensable part of most analytical instruments. There are many reasons for this pervasive presence. Perhaps most important is the ability of computers to perform repetitive tasks without variation (in the absence of hardware failure), which is critical to reproducible and defensible experimental results. Further, properly designed and implemented computer control/data systems maximize instrument and laboratory efficiency, resulting in higher sample throughput, faster results to the end-user, and increased profitability (either in terms of publications or currency) for the laboratory.

As a technique that arguably provides more chemical and structural information per unit sample than any other, MS has been employed in a variety of environments over its long history. The evolution of the mass spectrometer from a fundamental research tool for the elucidation of atomic and molecular properties to a benchtop turn-key instrument, in large measure parallels the evolution of both discrete and integrated electronic devices and computational hardware and software.

In this article no attempt is made to tabulate an exhaustive list of historical references to the application of computers in MS, but rather selected citations are presented to provide a flavor of the development in the field. There is one monograph dedicated to computers in MS,⁶ and the topic is given treatments ranging from cursory to complete in a variety of books on mass spectrometric techniques.

2.2 Early Devices

Early mass analyzers were spatially dispersive instruments, or mass spectrographs,⁷ utilizing static magnetic or DC (direct current) electric fields to perturb the
trjectories of accelerated ions. At the time of their development (ca. 1910–1920) photographic plates were placed in the focal plane of the spectograph, and after exposure to the ion beam an image was developed and the resulting data analyzed. Quantitative analyses were effected by comparing the amount of exposure on a film produced when the unknown sample was determined to calibrated plates developed after measuring known amounts of reference materials. This technique is still in use today in certain specialized (and somewhat archaic) applications. In the 1930s and 1940s detectors based on direct measurement of ion beam flux (such as the Faraday cup and electron multiplier), were introduced. Such detectors are single-channel transducers, and require that slits be positioned (in a dispersive instrument) to limit the exposure of the detector to a single mass at any given time. The signal is then amplified and recorded as a function of some independent variable (such as magnetic field strength, or the ion accelerating voltage) that is proportional to the mass-to-charge ratio (m/z) of the ions in the sample.

With the introduction of electronic detectors, it became practical to couple detector output to a digital computer via some type of interface. For low-intensity signals, such as measurement of discrete ions, pulse-counting techniques are employed. As this is inherently a digital process, transmission of data to a computer is relatively straightforward. Larger signals, characterized by significant and measurable detector currents, employ analog-to-digital converters (ADCs) prior to storage and manipulation on the computer.

2.3 Instrument Design

2.3.1 Time-of-flight

Time-of-flight (TOF) mass spectrometers were first developed in 1932, but the most familiar design, which forms the basis of current instruments, was described by Wiley and McLaren in 1955. Accurate measurement of ion time of arrival at the detector is key to achieving optimum resolving power and mass accuracy with this instrument. Prior to the introduction of computer data acquisition, oscillographic recording was required, with manual postprocessing.

2.3.2 Quadrupole

The quadrupole mass filter was first described in 1958. The advantages of this instrument include small size, low ion energy (volts rather than kilovolts for dispersive and TOF instruments), modest production costs, and the ability to quickly scan through a wide range of m/z values. As a result, this design has become by far the most popular variety of mass spectrometer. A related mass analyzer, the quadrupole ion trap, was not widely developed until the 1970s. Like the linear quadrupole mass filter, the ion trap is small, inexpensive, and robust. Both of these devices rely on the application of concerted radiofrequency (RF) and DC fields in order to define conditions under which ions have stable trajectories in the instrument.

2.3.3 Ion Cyclotron Resonance

The ion cyclotron resonance (ICR) mass spectrometer, first reported in 1968, relies on the absorption of RF energy and the natural precession of charged particles in the presence of a magnetic field for mass separation. Nominal resolving power is obtained in this instrument when operated in a continuous scanning mode, where the RF frequency is slowly swept and energy is absorbed when ions in the cell are resonant with the excitation. The most common incarnation of ICR is often referred to as FTMS, and spectral information is extracted from the digitally recorded decay and dephasing of ion orbits after a pulsed application of RF energy. This approach allows for significantly improved resolving power (1000-fold improvement) over the scanning experiment.

2.4 Computerization

As a result of the widespread availability of minicomputers in the late 1960s, and microcomputers in the 1970s and 1980s, automation of mass spectrometer control, tuning, data acquisition, and data processing became practical. The reduction in both size and cost of computational engines, with a concomitant increase in processing power, cannot be overemphasized in the development of automated data systems for mass spectrometers (and other analytical instrumentation). Certainly, the widespread implementation of gas chromatography/mass spectrometry (GC/MS) would have been significantly delayed without the availability of reasonably priced quadrupole mass spectrometers and minicomputer-based data acquisition and processing equipment. The operation of FTMS would be nearly impossible without the involvement of computers.

2.5 Brief Introduction to Artificial Intelligence and Expert Systems

Almost from the beginning of the digital computing era, both hardware and software engineers have been interested in developing computing tools that can monitor their environments, and subsequently make decisions and/or carry out actions based on rules either known a priori – from programming – or deduced – as a result of iterative observation/decision/feedback experiences. Such computational devices may be called ‘expert systems’, or may be said to operate based on ‘artificial intelligence’
intelligence’. It is certainly beyond the scope of this article to provide a complete history of AI and ES, but there are a multitude of both books and research articles related to this topic.\(^{14,15}\) Today, many parts of our world are monitored, and in some cases controlled, by automated, computerized equipment. In an effort to make these devices more responsive and efficient, many of them employ embedded ESs of varying degrees of sophistication. Programming languages such as LISP and PROLOG have been developed specifically to facilitate the development of software to implement AI and ES. The combination of powerful hardware, innovative algorithms, and capture of years of expert knowledge has allowed instruments to become increasingly independent of operator interaction, reducing the possibility for error and allowing the scientist to concentrate on the interpretation of the processed data and the formulation of new experiments.

\section*{2.6 Brief Overview of Artificial Intelligence and Expert Systems in Mass Spectrometry}

In the world of MS, AI and ES tools are used in three primary areas: optimization and control of the performance of the mass spectrometer itself, collection of the detector signal as a function of \( m/z \), and analysis of the data.

\subsection*{2.6.1 Spectrometer Control}

There are many instrumental parameters that need to be adjusted and held at an optimum value for best spectrometer performance. Initially, the instrument must be tuned, i.e. brought to a state in which peak intensity, peak shape, and mass calibration are all within acceptable limits. This is accomplished by introducing a known compound, such as PFTBA (perfluorotributylamine), into the spectrometer that produces a variety of well-characterized fragments over the mass range of interest, and adjusting (in an optimized fashion) the various instrument parameters to achieve the desired level of performance. Computers are almost invariably used to perform this task, because the adjustable parameters are often highly interrelated (repeller voltage, ion focusing lens potentials, electron multiplier voltage, mass scan rate, ion storage time, chemical ionization reagent gas pressure, time delay for ion extraction, etc.). Techniques such as simplex optimization are used to efficiently locate in parameter space the best-tune conditions. After tuning is complete, the computer can then monitor all of the vital signs of the instrument during operation, and alert the spectrometrist of marginal performance conditions, and even recommend appropriate interventions, before data quality is affected.

\subsection*{2.6.2 Data Collection}

In almost all data systems, the operator uses the computer to define the scope of the measurements to be made. Subsequently, the computer sets instrument parameters to control, for example, the speed of data collection, the mass range to be recorded, and other instrument type-dependent variables. As the experiment is performed, the computer records the detector signal via either a direct digital interface (for counting experiments) or an ADC. Correlation of the detector signal with the corresponding \( m/z \) condition is accomplished through a mass-axis calibration routine. Depending on the mass spectrometer type, this may be a DC, RF, or time reference.

\subsection*{2.6.3 Data Analysis}

After the data have been collected, their chemical information must be extracted and interpreted. There has been a significant amount of development in the area of data analysis software since the first report of such use in 1959.\(^{16}\) In this early work, a system of simultaneous linear equations were used to convert raw peak areas to normalized analyte mole fractions. A 17-component sample required 0.5–3 min of computing time for processing. Today, mixtures with nearly an order of magnitude more analytes can be reduced in less time, providing significantly more information than simply peak quantitation. In addition to quantifying analytes, mass spectrometer data systems routinely provide identification of species from their mass spectral fingerprints. One of the earliest examples of the application of AI to mass spectral interpretation was the work of Djerassi et al.\(^{17}\) A LISP (a list processing language)-based code, DENDRAL, was developed and subsequently applied to a variety of analyte classes. Most mass spectrometrists are familiar with spectral libraries, ranging from the print version of the so-called eight-peak index\(^{18}\) to the most modern computerized systems. The latter use intelligent peak-searching and pattern-matching algorithms to provide the operator with the most likely identities of species in a spectrum.

\section*{3 MASS SPECTROMETRY DATA SYSTEMS}

\subsection*{3.1 Introduction}

Since the mid-1970s the programming of mass spectral data systems has changed enormously. Although the basic tasks of an MS data system are fundamentally the same now as they were in the 1970s, many of the numbers involved have become substantially larger. In addition, developing mass spectral technologies such as FTMS have placed very heavy demands on the acquisition process.
Spectrum libraries have become larger. Analyses of large complex molecules (i.e. peptides) may consume a great deal of computer resources. Fortunately, the changes in computer and operating system technologies since the 1970s have been even more staggering than the changes in MS.

Section 3.2 defines the basic tasks of a MS data system. Section 3.3 describes the requirements imposed on the computers and operating systems that aspire to perform these tasks. Section 3.4 examines some of the specifics of how changes in computer technology have affected mass spectral data systems. Section 3.5 treats the subject of programmability. As the number of MS algorithms proliferate, the need for a data system to be customizable (i.e. programmable) has become ever more important – if users cannot define their own ways of collecting and analyzing data, unlimited computer power may be useless. Practical examples from actual data systems are presented, to show that the concerns of a programmer are often quite different from those of a chemist.

3.2 Fundamental Tasks of a Data System

The tasks of an MS data system are often neatly divided into instrument control, acquisition of data to a storage medium, and analysis of the data. The division is, of course, not really so simple. The collection of data depends significantly on simultaneous instrument control and the analysis of the collected data may be fed back into the instrument control. For example, in the process of tuning an instrument, the software may vary a variety of different parameters, each time collecting and assessing some data before trying a new set of conditions. In this case there is a feedback loop that involves control, acquisition, and analysis. The feedback must be very tightly orchestrated to be useful.

3.2.1 Instrument Control

The task of instrument control has several aspects – routine operation, instrument protection, tuning, and diagnostic programs. During routine operation many voltages must be set or scanned, and as much instrument status as possible must be read from the instrument. This status information may be stored with the data. It may be used to keep temperatures stable within the instrument by running PID (Proportional–Integral–Differential) loops on heaters. Or, it may be used to protect the instrument. For example, a sudden rise in pressure may indicate a leak and some voltages should be turned off. If mass peaks are saturated, perhaps the detector voltage should be decreased, or a warning message should be shown on the computer screen. The process of tuning and diagnostic programs, each in their own way, are microcosms of the entire MS data system. Those experienced in designing MS data systems have learned that it is advantageous to first write the diagnostic programs, basing them on very small and easily understood modules. These will, after all, be needed for the first evaluation of the instrument. It is then possible to base the ordinary operation of the instrument on these same modules. Doing so tends to provide the entire system with a relatively good structure. This bottom-up modular structure also makes it easy to add elementary operations (e.g. when adding new hardware) and higher-level operations can almost always be defined as combinations of the elementary processes.

3.2.2 Data Collection

The task of data collection is fundamentally important. Today’s computer operating systems are multitasking and therefore capable of running several processes at once. If the mass spectrometer is connected to a chromatograph or other time-dependent sample-introduction device, then the data collection must have priority over all other operations. A disaster can result if some data are missed. To guard against this, an MS data system may use more than one processor, dedicating at least one processor to data collection.

3.2.3 Data Analysis

Analysis of the collected data includes the following items:

- Conversion of raw (e.g. profile or Fourier-transform) data to mass peaks.
- Data display for the chemist.
- Enhancement of the data by background subtraction or other means.
- Use of the area under chromatogram peaks or other MS data to compare unknowns with standards and to achieve quantitative results.
- Library searching.
- Report generation.

A modern data analysis program includes other more advanced topics, which are covered elsewhere in this article; even the elementary operations listed above have many variations. Data systems must be flexible enough to allow the user to perform the operations in exactly the way and order required, hence the importance of programmability. The control, collection and analysis are all achieved through a user interface. This element of the data system determines the ways in which the user is able to enter information and communicate with the system. Section 3.4 looks at how changes in operating systems have affected the user interface and hence the ease of using mass spectral data systems.
It should be noted that, from the programmer's point of view, the design of an easy-to-use user interface is generally a much harder and time-consuming part of the programmer's task than implementing all of the chemical algorithms. The user interface includes the display of data and instrument status, as well as input devices such as menus and buttons that allow the user to control the system.

The display must respond to real changes in instrument status in a timely manner. For example, suppose that in the process of tuning an instrument the user is manually increasing a voltage setting by clicking a button on the screen. If nothing happens to the status display for more than a second, the user is very likely to click on the button again to accelerate the change in the system. This is simply because faster computer response time has naturally led to greater user impatience. However, overclicking can result in overshooting an optimum setting and this makes instrument adjustment almost impossible. Therefore, a crucial task of the data system to reflect the real-time status of the instrument.

3.3 Requirements for Operating Systems

As noted above, data collection must never fail. As the operating system used by a chemist is almost certainly a multitasking system, it is necessary to ensure that the highest possible priority is given to the data collection task. It must not be possible for other tasks to usurp the precious time required by the data collection procedures. This is the overriding concern in the selection of an operating system. For this reason Windows NT is a much more appropriate choice than Windows 95, for MS data systems. Several other operations also require high priority because they cannot be interrupted, such as those that involve delicate timing or real-time feedback.

If multiple processors are used, other requirements must be considered. For example, if an embedded processor in the instrument communicates with the data system over a serial or parallel line, it is important that the instrument be plug-and-play; that is, both sides should disconnect cleanly when the cable is disconnected and reconnect automatically when the cable is reconnected. If the embedded processor is depending on the data system for control and the connection is broken, the embedded processor should go into a standby state for safety purposes.

Most instrument manufacturers have chosen to base their data systems on PCs running Microsoft operating systems. A brief survey of 22 instrument manufacturers found that 18 of them were using a version of Microsoft Windows. Others used OS/2, and operating systems from Hewlett-Packard, Sun, and Apple.

3.4 Impact of Continuing Advances in Computers on Mass Spectrometry Data Systems

The most obvious improvements in computers have been the dramatic increases in speed and in the size of computer memories and storage. The forefathers of today's data systems were developed on home-built computers using Intel chipsets or on systems produced by Data General, Digital Equipment, Commodore, or Apple (section 2). These systems typically had 16–64 kB of ram and sometimes included a 5 or 10 MB disk. Since the 1970s the availability of memory and storage has increased by over three orders of magnitude. Execution times have also increased, albeit to a lesser extent. For example, library searches are now four to eight times faster.

Operations that require large arrays of data and massive amounts of arithmetic have benefited most from the improvements in hardware design. These improvements have also made it much easier to implement algorithms. Previously, developers had to implement programming tricks to handle very large arrays of data. Activities such as library searches required extensive coding in order for their execution to be completed in a reasonable amount of time. Today even more advanced and thorough searches can be implemented with a few lines of C code. These advantages also apply to algorithms written by the user of the data system (if a programming language is available – see section 3.5).

Networks are beginning to have a major impact on data systems. Local networking provides a great advantage by giving the user a wide variety of high-capacity storage options. The internet allows easier transfer of data and results, but has found only limited use in instrument control. In both cases security issues are a major concern. Although most laboratory management systems provide security features, such as passwords, etc. the proper set-up and administration of these controls is required. This may be beyond the resources of some laboratories and is clearly an added cost.

The current operating systems have had a significant impact on the standardization of user interfaces. In the first mass spectral data systems, each had different ways to enter commands or click with a mouse. It was therefore a major challenge to instruct users on how to use a data system. In some cases the operator had to develop significant programming skills to use the system. In current user interfaces many operations, such as cut and paste, are standardized on the computer. As these are performed in the same way in most computer programs, everyone who has worked with a computer is well-versed in the art of using menus and mouse clicks to interact with a computer program. The fact that a large majority of data systems are based on Windows makes this even more true. Chemists now have a much easier time learning
to use new data systems because they already have a good idea of how the user interface will work. This standardization has produced the one drawback, in that many programs now look the same and it is becoming a challenge for programmers to make their systems unique and original.

3.5 Programmability

As discussed above, many aspects of modern mass spectral data systems require that they be programmable (or customizable). Every system is limited to have a finite number of built-in operating modes and algorithms. The chemist, therefore, needs to have the ability to mix modes and tailor algorithms to suit experimental objectives. The programmer who writes the data system is not able to anticipate which aspects of an algorithm the user may wish to vary, so ultimately the user needs to be able to program functions into the system. This section describes the elements that a system must include, to be truly programmable.

First the user needs a language to write algorithms in. The language needs to incorporate basic arithmetic and common math functions. It also needs to have program flow control elements such as loop and logic structures (‘if’, ‘while’, and ‘repeat’). The user needs to be able to use predefined variables such as ‘first_mass’, ‘last_mass’, ‘detector_voltage’. They also need to control MS operations with built-in commands such as ‘Do_one_scan’, ‘filament_on’, ‘filament_off’. The language must have built-in feedback so that decisions can be based on the state of the instrument or the nature of the data. Functions such as ‘Source_temperature’ or ‘Manifold_pressure’ can serve this purpose. The most advanced systems include functions such as ‘Intensity of mass 278 in the last data-set’ or ‘Mass of the biggest peak in the last data-set’ that return facts about the data.

The language should to be able to perform all control, collection, and analysis steps. It ought to be possible to run more than one process at once, so that the system can collect one set of data while analyzing another, and perhaps reporting on a third. For good laboratory practice, it is important to have functions to write any sort of information into a file. This will ensure that every dataset has enough information stored within it to show exactly how it was acquired. It also allows diagnostic programs to keep track of instrument performance over any period of time.

The feedback functions in the language can be used for a wide variety of algorithms. For example, in the arena of safety, the chemist can specify the actions to be taken if a temperature or pressure gets too high. Alternatively, the chemist could write a tuning loop that sets a voltage, collects a scan of data, and reads back information about a peak.

Section 3.5.1 includes a number of illustrative examples. The procedures are written in a pseudocode quite similar to an actual programming language. The first example shows the optimization of data collection by timing acquisition. The second is part of an autotune algorithm. The third is a higher-level procedure for automatic quantitation, meant to run continuously in the background.

3.5.1 Example 1: Timed Acquisition

One can increase the amount of analytically relevant information by only collecting data that is appropriate for the retention time. The following routine is for an MS/MS instrument that does single reaction monitoring of several different reactions, 219–69 for the first two minutes, 512–69 for the next two minutes and 131–69 thereafter:

```plaintext
start_collection
srm(219,69)
while retention_time < 2:scan:end
srm(512,69)
while retention_time < 4:scan:end
srm(131,69)
while retention_time < 10:scan:end
end_collection
```

The functions referred to have the following meaning:
- `srm(m1,m2)` means set the instrument to monitor the reaction `m1–m2`.
- `scan` means collect one scan of data.

3.5.2 Example 2: Tuning

This is an example of a tuning algorithm called ‘optimize_lens’; it’s one argument specifies which lens to tune. While tuning, the system collect raw data. For these data, ‘height’ refers to the height of the biggest peak in the dataset. As before, ‘scan’ means collect one scan of data. The items ‘biggest_area’ and ‘best_lens’ are temporary variables. The goal of the procedure is to find an optimum value of a lens.

```plaintext
optimize_Lens(n)
biggest_height = 0
for lens(n) = -100 to 0 in steps of 1
  scan
  if height >= biggest_height
    biggest_height = height
    best_lens = lens(1)
end
end
lens(n) = best_lens
```
When this is done, lens \( n \) will have been optimized. Such a routine may be built into a higher level routine:

```
optimize_all_lenses
optimize_lens(1)
optimize_lens(2)
optimize_lens(3)
```

This process may be abstracted to as high a level as required.

3.5.3 Example 3: Automatic Quantitation

If the data system is designed properly, rules can be defined to run continuously in the background. Here is an example of a high-level algorithm that provides automatic updating of a quantitation list when the chemist changes the calculations for one of the compounds in the list. For example, suppose the user has collected several data files, including analytes and internal and external standards. They have quantitated a set of compounds in these data files, using mass chromatograms to obtain an area for each unknown or standard. The areas and concentrations of the standards are used to create a response curve. The areas of unknowns are used, in conjunction with the response curve, to calculate the unknown concentrations. One now has a list of areas and quantities for each compound, along with the information on how they were computed. If the user were to change the area of one of the standard compounds by changing the parameters that went into its calculation, we would like to see the amounts of all related peaks change correspondingly. Here is an example of a procedure that performs this operation.

```
Repeat-forever
  if some_compound_changed
    for r = 1 to number_of_response_points
      c = external_standard(r)
      c1 = internal_standard(r)
      response_x(r) = compound_area(c)/compound_area(c1)
      response_y(r) = compound_amount(c)/compound_amount(c1)
    end
    for c = 1 to number_of_compounds
      compute_amount(c)
    end
  end
  Sleep_one_second
end
```

The functions referred to have the following meanings:
- `some_compound_changed` set to ‘True’ if any one of the compounds in the list changed area or amount, which means that ‘compound_area’ or ‘compound_amount’ changed for that compound.
- `number_of_response_points` the number of points in the response list.
- `external_standard(r)` the compound number of the external standard at position \( r \) in the response list.
- `internal_standard(r)` the compound number of the internal standard at position \( r \) in the response list.
- `compound_area(c)` the area under the chromatogram for compound \( c \).
- `compound_amount(c)` the calculated or given amount of compound \( c \).
- `number_of_compounds` the number of compounds in the list.
- `compute_amount(c)` computes the amount of compound \( c \) from its area and the response list.
- `sleep_one_second` prevents the procedure from hogging the system – there is no need to check more than once a second that the user has changed the data.

This procedure checks whether some compound has changed area or amount (changed by the user). If so, it recalculates the response curve by filling in each point on the response curve from the areas and the amounts of the appropriate compounds. Then, for each compound, it computes the amount of that compound (‘compute_amount’ uses the response curve). If the display of data is responsive to changes in the data, the user will see all areas and amounts change as soon as one value is changed. In section 3.2 an example was given of the necessity of a close link between data and display; this procedure is another example.

To keep the code simple, this example assumes that there is only one response list involved. However, it is easy to extend the code to a system that includes several response lists.

These examples give an indication of how programmable a data system can be. The challenge for the
designers of data systems is to balance flexibility with simplicity for the sake of the chemist who is content with the basic operation of the system. MS is not a trivial task and operating a mass spectral data system is likely to remain a challenging task as the functionality of MS data systems continues to expand. Hopefully, the user interface, which is what makes it possible to use all this functionality, will keep pace.

4 BIOLOGICAL APPLICATIONS

4.1 Protein Sequence Determination

MS has long had as its goal the ability to determine the sequence within polymeric biologically important molecules, such as DNA and proteins. There have been notable advances in this area in the period 1990–1999. However, the goal of developing a simple yet general method for rapidly sequencing these molecules by MS has remained elusive.

Fortunately, alternative approaches have been introduced that take advantage of the large amount of DNA and RNA sequence information that has been generated by genome sequencing projects and which is currently stored in databases. Using this nucleic acid sequence information, it is possible to determine whether the results of a mass spectrometric experiment correspond to a sequence in a database. If such a correspondence exists, it is no longer necessary to sequence the protein (or corresponding RNA) by MS or other means – the answer can be simply read from the database. If the database information is incomplete, it can serve as a starting point for other studies, greatly reducing the experimental work required for the determination of the full sequence.

4.1.1 Peptide Cleavage and Extraction

All protein sequence identification experiments begin with the creation of a set of smaller oligopeptide molecules from the intact protein. The patterns generated from these oligopeptides are then used to search nucleotide sequence databases. These oligopeptides (frequently referred to simply as ‘peptides’) are produced by the action of a reagent that cleaves the protein’s peptide bond backbone at sequence-specific sites, such as peptide bonds that are adjacent to a limited set of amino acids. Peptide digesting enzymes, such as trypsin or endopeptidase Lys-C, are commonly used for this purpose. Reactive amino acids, particularly cysteine residues, are protected with chemical reagents that prevent them from modification during the process.

4.1.2 Dataset Generation – Mass Spectrometry, Matrix-assisted Laser Desorption/Ionization and Electrospray Ionization

Once the oligopeptides have been generated, the masses of all of the peptides generated from a protein can be measured at once, using matrix-assisted laser desorption/ionization (MALDI) or electrospray ionization (ESI) ion sources, mounted on a variety of different types of mass analyzers. Analysis using a MALDI ion source is currently the most common method, but the use of sophisticated deconvolution will make ESI a viable option. Proteins produce patterns containing 10–1000 isotopic peak clusters, depending on the sequence of a particular protein. Each peak cluster represents a particular peptide sequence.

Alternatively, the ions corresponding to an individual peptide from a protein digestion can be isolated, either using chromatography or MS/MS techniques. The resulting ions can then be fragmented in a gas phase collision cell producing a pattern of masses characteristic of the sequence of the original peptide (MS/MS or MS/MS/MS, i.e. MS$^n$). This pattern can be used to search databases, using the accumulated knowledge of the preferred gas-phase peptide bond cleavage rate constants. The resulting pattern is strongly affected by the time elapsed between collision and measurement of the product ion distribution, so different rules must be applied for different types of MS/MS analyzers.

4.2 Database Search Strategies

The data sets generated by mass spectrometric experiments can be compared to the nucleotide sequence information present in databases in several ways. All of these methods share some common features. In order to compare sequences, the chemical reactions involved in producing the cleaved peptides are simulated, producing a theoretical set of peptides for each known protein sequence in the database. This simulation can either be done during the search process or a specialized database consisting of the peptides resulting from a particular cleavage and protection chemistry can be prepared in advance. The simulations are then compared to the experimental data, either using specialized correlation functions or using multiple-step discrete pattern matching. This comparison is done by assuming that sequences that correspond to the experimental data set will contain a set of peptides with masses that agree with the experimental data, within some experimental error.

4.3 Nucleotide Databases

Databases of complete gene sequences can be searched as though they were protein sequence databases. The
existence of known start codons and intron/exon assignments allows the use of, either MS or MS$^n$ patterns. Nucleotide databases that contain incomplete sequence information, such as the database of expressed sequence tags (dBEST),$^{25}$ present special challenges. In this type of database, there are six possible peptide sequences for each nucleotide sequence and each must be searched independently. The short length of the sequences makes the use of MS-only data impractical; these databases require the use of MS$^n$ fragmentation patterns.

4.3.1 Annotated Protein Databases
Dedicated protein sequence databases that store annotated oligopeptide translations of nucleic acid sequences are the best databases for any MS-related search strategy. The annotations in the database indicate what is known about post-translational modification of the protein, allowing the chemical cleavage simulation to be performed more accurately than is possible using nucleotide information alone. The number of protein sequences in this type of database is still very limited—annotation is time-consuming and only possible when detailed experimental results are available for a particular sequence.

4.3.2 Confirmation and Scoring Results
The results of comparing a set of experimental masses to a sequence database usually results in the identification of a number of candidate sequences that match to some extent with the experimental data. The task of distinguishing random matches from the ‘correct’ match has been approached in a number of ways. The simplest scoring system involves counting the number of masses that agree within a given error and reporting the sequence with the most matches as being the best candidate sequence. This approach is very simplistic and frequently deceptive. More sophisticated scoring schemes involve appraising pattern matches on the following criteria:

- sequence coverage – the fraction of the candidate protein represented by the experimental masses;
- sequence distribution – the pattern of matched peptides in the candidate protein;
- mass deviation – the pattern of experimental mass deviations from the simulation values;
- statistical significance – the likelihood that the match could have occurred at random.

Research into the appropriate scoring scheme for MS and MS$^n$ match scoring is still ongoing. The most successful of scoring systems will be the basis for the next generation of fully automated protein identification instruments.

Currently, none of the protein identification algorithms make use of AI or algorithm training methods. The Profound algorithm is currently the closest to using AI—it uses a Bayesian statistical approach to evaluating data sets, allowing for the unbiased evaluation of search results and for the detection of multiple sequences in a single MS data set.$^{26}$

4.4 Protein Modification Analysis
MS may have limitations in the determination of protein sequences de novo, but it is very well suited to the detection of chemical modifications of a known sequence. The detection of these modifications is very dependent on good software as there is too much information for manual data reduction. The general strategy is very similar to that used to identify proteins, a process that grew out of the standard practice for finding modifications. The general strategy is as follows: determination of the intact protein molecular mass; cleavage to peptides; generation of mass spectra; and automated, detailed comparison of the MS data set with a known sequence.

4.4.1 Peptide Cleavage and Extraction
The cleavage and protection chemistry available for detection of modifications is much broader than that used in protein identification experiments. Any proteolytic enzyme, chemical cleavage or protection method can be used, depending on the type of modification sought. Popular endoproteinase enzymes are trypsin, endoproteinases Lys-C and Asp-N, and Staph. V8 proteinase.$^{27}$ Exopeptidases, such as carboxypeptidase A, B, and P can also be useful for generating C-terminal sequencing ladders for smaller peptides.$^{28}$ Unlike the protein identification procedure, it is very useful to follow a time course of protein cleavage, as the dynamics of proteolysis can provide valuable clues to the identity and location of modifications. Chemical cleavage reagents, such as cyanogen bromide, iodosobenzoic acid and hydroxylamine, can be used in place of enzymes. These reagents are less popular than enzymes, because of their propensity for producing complicating modifications in the sequence through side-reactions.

4.4.2 Generation of Mass Spectroscopy Datasets
Mass spectroscopy datasets are collected in the same way as for protein identification experiments. Typically, a number of experiments are run, using different cleavage reagents with different and complementary specificity. For example, both a trypsin and endoproteinase Asp-N digest would be both run, taking several time points during the reaction to reconstruct its time course. All of the data collected is stored for later analysis.
Datasets for MS can be prepared that greatly assist analysis in the detection of common modifications, such as phosphorylation or disulfide cross-linking. These modifications produce characteristic fragmentation signals following gas-phase collisions. The most popular method for collecting this type of specialized data is directly coupling the output from high-performance liquid chromatography (HPLC) to an MS/MS device (such as a triple quadrupole or an ion trap analyzer) and flagging spectra that contain these characteristic signals.

4.4.3 Comparison with Sequence

Once a dataset has been assembled, it must be compared with the results that would be expected from the predicted amino acid sequence. For a simple enzymatic cleavage experiment on a protein that has 30 theoretical cleavage sites (N) and no cystines, there are approximately 450 possible product peptides. The complexity of the task of examining a dataset for each of the possible products and locating the peaks that do not agree is clearly too time-consuming and error prone to be performed manually.

The majority of data is analyzed using automated systems to assist the investigator—no system that performs a complete and reliable analysis is currently available. Modern analysis is performed by first determining the mass of a peak in the MS dataset and searching a sequence for a peptide with a mass that is within a user-defined error of the experimental value. The dataset can be a single mass spectrum containing all of the cleaved peptides or an HPLC/MS dataset that contains thousands of individual spectra, each of which will contain zero or more of the peptides, depending on the chromatographic conditions.

The best analysis systems use a multifactorial fuzzy-logic-based approach to analyzing the data. The entire dataset is interrogated and individual matches rated with respect to all of the other assignments. Peptides with the same mass (within the allowed error) are assigned based on the kinetics of the cleavage reaction, as inferred by the fuzzy logic rules. Peaks that can be assigned by mass, but which are unlikely based on the entire data set, are flagged for further examination and confirmation. These flagged peaks, as well as those that could not be assigned are then iterated through a selection of known modifications and the complete sequence assignment process repeated. The fuzzy logic assignments depend on the entire dataset so the change of value in the simulated experiment requires a complete reexamination for the assignments.

Once this iterative process is finished, the results can be projected back onto the theoretical sequence, with each assignment flagged and color coded so that interesting portions of the sequence are displayed. This process is particularly effective if the three-dimensional structure of the protein is known, where the peptides can be located in a structure diagram shown in a stereoscopic display.

4.5 Use with Differential Displays

Differential displays are a particularly useful tool in current cell biology. They consist of some type of high-resolution protein separation system, such as two-dimensional gel electrophoresis, and a signal detection process such as affinity or silver staining. A cell challenged in various ways will produce displays that differ as the protein complement being expressed in the cell changes. By overlaying displays, spots that change are apparent. The challenge is then to determine what protein has appeared (or disappeared or changed positions).

The techniques described in sections 4.1–4.3 can be applied to these displays. By excising interesting areas of the separation bed and extracting the protein components in various ways, the protein sequence can be rapidly identified. A new generation of automated differential display devices utilizing MS as a protein identification system is currently being designed. These instruments will replace the current practice of manual sample preparation and mass analysis, although the protein identification algorithms will remain the same. The fully automated instruments will probably perform best on data derived from species with known genomes.

4.6 Alternate Splicing

When a eukaryotic organism translates its DNA into RNA in the nucleus (the primary transcript), the transfer RNA is usually edited before it is exported out of the nucleus as transfer RNA for transcription into a peptide chain. This editing process, generally referred to as RNA splicing, involves the removal of portions of the RNA that do not code for peptide sequence (exons), leaving the portions that do code for sequence and transcription regulatory functions (introns). In multicellular organisms with differentiated cell and tissue types—which includes all animals and plants—different exons can be spliced into the transfer-RNA in different cell types, resulting in different protein sequences that originate from the same gene. These different proteins that originate from the same gene are called ‘alternate splices’. The regions of genomic DNA that will be deleted or included can be predicted with some accuracy for the most likely transfer-RNA product; however, the alternate forms cannot be predicted in advance and they must be discovered experimentally.
Protein identification-type experiments are ideally suited to the rapid identification of alternately spliced proteins. In order to distinguish alternate splicing from proteolytic processing, the existing generation of protein recognition algorithms will need to include a method for searching and scoring multiple gaps using the genomic sequence as a starting point. By using predicted exon/intron divisions, it should be possible to search the possible DNA-to-RNA translation sequences to determine whether an alternate splice form is present in a particular differential display. Such a search is beyond the capabilities of the current generation of software: they all require an accurate RNA translation. However, with the introduction of AI-type training capabilities, it should be possible to apply the most sophisticated of the current algorithms to this problem.

5 MASS SPECTROMETRY APPLICATIONS OF PRINCIPAL COMPONENT AND FACTOR ANALYSES

5.1 Introduction

PCA calculates an orthogonal basis (i.e. coordinate system) for sets of mass spectra for which each axis maximizes the variation of the spectral dataset. Each axis is represented as a vector that relates the linear dependence of the mass spectral features (i.e. m/z variables). Typically, the new coordinate system has a reduced dimensionality. The PCA procedure allows the scientist to compress the data, remove noise, and discover the underlying or latent linear structure of the data.

FA rotates the principal components away from directions that maximize variance towards new chemically relevant directions; it allows scientists to resolve underlying pure components in mixtures, build classification models, and determine mass spectral features that relate to specific properties such as concentration or class.

5.2 Selected History

When computers were interfaced with mass spectrometers, numerical calculations could be used to simplify the data. A brief and somewhat selective history follows. The PCA technique was developed for the study of psychological measurements that are inherently complicated by many difficult-to-control factors.29 These factors can be attributed to the different environmental, behavioral, or genetic influence on the human subjects who are evaluated. Some method was needed that would determine which factors were important and which factors were correlated.

The earliest applications of PCA in analytical chemistry determined the number of underlying components in mixtures. Specifically, for optical measurements, a mixture could be effectively modeled by a linear combination of the spectra of the pure components. The number of pure components of the mixture would correspond to the rank of the data matrix. The rank of a matrix of optical spectra of mixtures was computed using Gaussian elimination.30,31 The application of FA to solving problems in chemical analysis was pioneered by Malinowski et al.32,33

The applications of PCA and FA to gas chromatography (GC) and MS first occurred in the 1970s. Initially, FA was employed to study the relationships between chemical structure and GC retention indices.34–37 Then PCA was demonstrated as a tool for deconvolving overlapping GC peaks.38 Next, FA was applied to 22 isomers of alkyl benzenes to assist the interpretation of fragmentation pathways and as a method for compressing the mass spectra to lower dimensionality.39,40 The FA method was used for classifying mass spectra.41

The coupling of multichannel detection, specifically MS to GC, allowed PCA and FA to resolve overlapping components of GC/MS peaks.42,43 The target transform FA method was automated for GC/MS analysis.44

FA was initially applied to solving problems of overlapping peaks in GC/MS. Soon it was realized that FA was a useful tool for the analysis of complex mixtures such as biological (bacteria, proteins, and hair) and geological (coal, atmospheric particles, and kerogen) samples. These complex samples were all amenable to pyrolysis mass spectrometry (PyMS).45 The discriminant and FA were applied to various biological samples.46 An unsupervised graphical rotation method was developed and applied to geological samples.47 Canonical variates analysis (CVA)48 was used to take advantage of measurement errors furnished by replicate spectra and was combined with rotation for mixtures of glycolen, dextran, and bovine serum albumin,49 and has become one of the methods of choice for the analysis of MS fingerprints from bacteria.50 The FA method was demonstrated as an effective tool for analysis of smoke particles by PyMS.49 A related method that exploits PCA for classification is soft independent modeling for class analogies (SIMCA).51

Other techniques that benefited from FA and PCA are laser ionization mass spectrometry (LI/MS),52 fast atom bombardment mass spectrometry (FAB/MS),53 electrospray MS,54 and secondary ion mass spectrometry (SIMS).55 In the SIMS work, cluster analysis was used to help align high-resolution mass measurements into optimized columns of the data matrix, which was evaluated using PCA.
5.3 Introductory Example

A brief demonstration of PCA and FA is presented with accompanying graphs. A data set of mass spectra was obtained from the Wiley Registry of Mass Spectra, 5th edition,\(^ {245}\) that comprised spectra of hydrocarbons that were alkane, alkene, or diene. This data matrix is exemplary because the MS fragmentation patterns are easy to predict. These data were part of a larger project that built classification models for identifying spectra of plastic recycling products.\(^ {56}\) The data matrix was composed of 527 spectra and 95 columns that correspond to \(m/z\) values. The \(m/z\) values ranged from 50 to 144. Typically, if all the spectra have no mass peaks at a specified \(m/z\), this column is excluded from the data matrix. Table 1 gives the design of the hydrocarbon data set.

The principal components were calculated by singular value decomposition (SVD)\(^ {57}\) in a Win32 program that was written in C++. The analysis of these data required less than 5 s on a 300 MHz PC computer with 128 MB of random access memory and operating under Windows 98 in console mode.

The spectra were preprocessed by normalizing to unit vector length and centering the spectra about their mean spectrum before the PCA. Figure 1 gives the eigenvalues with respect to the component number. The eigenvalues measure the variance spanned by each eigenvector. For intricate data sets, the eigenvalues typically asymptotically approach zero. The relative variance of each eigenvalue is calculated by dividing the eigenvalue by the total variance of the data matrix. The total variance is easily obtained as the sum of the eigenvalues. From this calculation, the first two principal components account for approximately half the variance in this data set.

Examination of the mass spectral scores on the first two components in Figure 2 shows that the spectra tend to cluster by class (i.e. degree of unsaturation). The first component has the largest range of values and is responsible for separating the spectra in order of diene, alkene, and alkane. This component can be investigated further using the variable loadings in Figure 3. This graph shows the principal component plotted with respect to \(m/z\), so that key spectral features may be investigated.

The principal components point in mathematically, but not necessarily chemically, relevant directions. Target transform FA was used to rotate 13 principal components that spanned 95% of the variance in directions that correlate with the specific structural classes of the spectra. Figures 4–6 give the rotated factors for the diene, alkene, and alkane classes. Notice that the periodicity of the fragmentation pattern is precisely as one would expect for these sets of data. The alkenes follow a pattern of carbon number times 14, the dienes follow the same pattern except shifted to two less, and the alkanes shifted by two more. The shifts account for the change in mass of the molecule by the loss of two hydrogen atoms for each degree of unsaturation.

### Table 1

5.4 Theoretical Basis

5.4.1 Principal Component Analysis

Typically, data are arranged into a matrix format so that each row corresponds to a mass spectrum and each column to a measurement at a specific \( m/z \) value. This matrix is designated as \( D \). The PCA method is mathematically based on eigenvectors or eigenanalysis.

The method decomposes a set of data into two sets of matrices. The matrices are special in that the columns point in directions of major sources of variation of the data matrix. These vectors are eigenvectors. (Eigen is the German word for characteristic.) Because these vectors already point in a direction inherent to the data matrix, they will not change direction when multiplied by the data matrix. This property is referred to as the eigenvector relationship and is defined as Equations (1) and (2):

\[
D^T D v_i = \lambda_i v_i \quad (1)
\]
\[
D D^T u_i = \lambda_i u_i \quad (2)
\]

where \( D^T D \) is a square symmetric matrix that characterizes the covariance of the columns of the data set \( D \). \( v_i \) is eigenvector \( i \) that is in the row-space of \( D \), and \( \lambda_i \) is eigenvalue \( i \). In Equation (2), \( D D^T \) is a square symmetric matrix that characterizes the covariance of the rows of the data set and \( u_i \) is in the column-space of the \( D \).

Besides maximizing the variance, the sets of eigenvectors form orthogonal bases. This property can be expressed by Equations (3) and (4):

\[
V^T V = I \quad (3)
\]
\[
U^T U = I \quad (4)
\]
for which \( \mathbf{V} \) is a matrix comprising row-space eigenvectors \((v_i)\) and \( \mathbf{U} \) is a matrix comprising column-space eigenvectors \((u_i)\). The identity matrix \( \mathbf{I} \) comprises values of unity along the diagonal and values of zero for all other matrix elements. The relationship given in Equations (3) and (4) is important because it shows that the transpose of an orthogonal matrix is equal to its inverse.

For large sets of data, computing the covariance matrix is time-consuming. A method that is precise and fast for computing both sets of eigenvectors is SVD:\(^{58}\)

\[
\mathbf{D} = \mathbf{USV}^T
\]  

(5)

From Equation (5) \( \mathbf{D} \) can be decomposed into the two matrices of eigenvectors and a diagonal matrix \( \mathbf{S} \) of singular values (Equation 6):

\[
\lambda_i = \sigma_i^2
\]  

(6)

The singular values \( \sigma_i \) are equal to the square root of the eigenvalues, which leads to another important property that is given by Equation (7):

\[
\mathbf{D}' = \mathbf{US}'\mathbf{V}^T
\]  

(7)

This relationship is important because any power of \( \mathbf{D} \) can be calculated by decomposing the matrix, raising the diagonal matrix of singular values to the \( n \)th power, and reconstructing the matrix. A useful power is negative unity, because \( \mathbf{D}^{-1} \) can be used for calculating calibration models. Furthermore, pseudo-inverses can be calculated from singular or ill-conditioned data matrices by reconstructing using only the components (i.e. vectors) that correspond to singular values above a threshold.

The other important element of PCA is the concept of a principal component. Because the row-space and column-space eigenvectors are orthogonal and hence independent, the number of eigenvectors will always be less than the dimensionality (i.e. minimum of the number of rows or columns) of \( \mathbf{D} \). The number of nonzero eigen or singular values gives the mathematical rank \( r \) of \( \mathbf{D} \). The rank gives the number of underlying linear components of a matrix. However, besides mathematical rank, there are physical and chemical ranks. The physical rank gives all the sources of variances that are associated with the physics of obtaining the measurement including noise. These variances may correspond to background or instrumental components. The chemical rank corresponds to variances related to the chemical components of interest. Therefore, the mathematical rank is the number of components with eigenvalues greater than zero. The physical rank corresponds to eigenvalues greater than a threshold that characterizes the indeterminate error of making the measurement. The chemical rank is typically the smallest and corresponds to the number of chemical components, when the variances of the data follow a linear model.

Typically, the components that are less than either the physical or chemical ranks are referred to as principal components. The components that correspond to the smaller eigenvalues are referred to as secondary components. Secondary components usually characterize noise or undesirable variances in the data. The determination of the correct number of principal components \( r \) is important. If the number of principal components is too small then characteristic variances will be removed from the data. If the number of principal components is too large then noise will be embedded in the components as well as signal. There are several methods to evaluate the calculation of the correct number of principal components.

One of the simplest methods is to reconstruct the data \( \mathbf{D} \) using subsets of the eigenvectors. When the reconstructed data resemble the original data within the precision of the measurement, then the proper number of principal components has been obtained. An empirical approach determines the minimum of the indicator function (IND), which is not well understood, but furnishes reliable estimates of the chemical rank.\(^ {59}\)

There are three key pieces of information furnished by PCA. The first is the relationship of the variance that is spanned by each component. Plotting the eigenvalues as a function of components, gives information regarding the distribution of information in the data. The eigenvalues also convey information regarding the condition number of the data matrix. The condition number is obtained by dividing the largest eigenvalue by the smallest. This condition number can be used to assess the error bounds on a regression model\(^ {60}\) and as a means to evaluate selectivity.\(^ {61}\)

This approach was what made PCA useful for assessing the number of analytical components contained in a GC peak. This methodology is still used; however, it is referred to as window or evolving factor analysis (EFA). Instead of processing the spectra contained in a chromatographic peak, a window (i.e. a user-defined dataset) can be moved along the chromatogram. The chemical rank is evaluated and gives the number of chemical components in the window.

The second piece of information is furnished by the observation scores. Score plots display the distribution of spectra or rows of \( \mathbf{D} \) in a lower dimension graph. The scores of the first two components provide a two-dimensional window that maximizes information content of the spectra. If the rows are ordered with respect to time, the observation scores give trajectories of the changes that occur in the data over time (Equation 8):

\[
\mathbf{o}_i = \mathbf{d}_i \mathbf{V} = \mathbf{u}_i \mathbf{S}
\]  

(8)

for which \( \mathbf{o}_i \) is a row vector of the \( i \)th observation score of spectrum \( \mathbf{d}_i \). This may be calculated by multiplying
a spectrum or the \(i\)th row of \(D\) by the matrix of principal components. The observation scores can be calculated directly for the results of SVD by multiplying the matrix of singular values \(W\) by the \(i\)th row of the column-space eigenvectors \(U\). Plots of the observation scores are also referred to as the Karhunen–Loève plots. These plots allow clustering of the data to be visualized.

The final piece of information is yielded by the variable loadings, which indicate the direction that the row-space eigenvectors point. The variable loadings show the importance of each variable for a given principal component. Plots of variable loadings can be examined for characteristic spectral features. They also are used together with the observation score plots to see which spectral features are responsible for separating objects in the score plots.

In some instances, the data matrix \(D\) can be modified so that the principal components point in directions that are more chemically relevant. These modifications to \(D\) are referred to collectively as preprocessing. Typically, the spectra are mean-centered, which refers to subtracting the average spectrum from each spectrum in the dataset. This centers the distribution of spectra about the origin. If the data are not mean-centered, the first principal component will span the variance characterized by the overall distance of the data set from the origin.

In some cases, the spectra are normalized so as to remove any variations related to concentrations. Normalization scales the rows of \(D\), so that each row is weighted equally. Mathematically, normalizing the spectra to unit vector length will achieve this equalized weighting. For spectra that vary linearly with concentration, the concentration information is manifested in the vector length of the spectrum. Other methods of normalization include normalizing to a constant base peak intensity (i.e. maximum peak of unity) or to a constant integrated intensity (i.e. sum of peaks of unity).

The data may be scaled so that the variables or columns of \(D\) are weighted equally. Scaling is important for mass spectra, because peaks of higher mass that tend to convey more information, have smaller intensities, and tend to be less influential in the calculation of principal components.

Autoscaling gives each variable or column of data equal weight. This method of scaling is useful when the noise or the signals are not uniformly distributed across the mass range. For this method of preprocessing, each column of \(D\) is divided by its standard deviation. The problem with autoscaling is that variables that convey noise only are weighted equally. Scaling is important for mass spectra because peaks of higher mass that tend to convey signal. A better approach is to scale the data by the experimental errors for each variable. Experimental error can be measured as the standard deviation of replicate spectra. The variances of these standard deviations can be added for different samples to calculate an estimate of the experimental error. The experimental error avoids the diminution of the signals during scaling.

An alternative to scaling is transformation. In some cases the data may be converted to the square root or logarithm to give greater weight to smaller features. A useful method for preprocessing mass spectra is through modulo compression.\(^{62}\)

### 5.4.2 Canonical Variates Analysis

For supervised classification, a useful method related to PCA is CVA,\(^{63}\) which is also applied with discriminant (function) analysis.\(^{64}\) The CVA method is not usually performed on the original feature space (mass spectra) because the mass spectra have colinear variables or too many variables for CVA. This problem may be resolved by compressing the data, such as using principal component scores\(^{65}\) or by calculating the pseudo-inverse of the covariance matrix.\(^{65}\) The canonical variates (CVs) are principal components that are calculated from a matrix that is related to Fisher variance and analysis of variance. In the traditional method, two covariance matrices are calculated. The first matrix characterizes the covariance of the class means about the grand mean of the data. The second matrix characterizes the variation of the spectra about their class means.

The CVA approach uses PCA twice in the calculation. First, SVD is used to compute the pseudo-inverse of the within-groups sum of squares matrix (\(SS_w\)). The CVs are the variable loadings obtained from PCA applied to \(R\), which is obtained by Equation (9):

\[
R = SS_b SS_w^{-1}
\]  

for which \(SS_b\) is the between-class sum of squares matrix and \(SS_w\) is the pseudo-inverse of the within-class sum of squares matrix (\(S_w\)). These are calculated by Equations (10) and (11),

\[
SS_b = \sum_{i=1}^{N_i} N_i (\bar{x}_i - \bar{x})(\bar{x}_i - \bar{x})^T
\]

\[
SS_w = \sum_{i=1}^{N_i} \sum_{j=1}^{N_i} (x_{ij} - \bar{x}_i)(x_{ij} - \bar{x}_i)^T
\]

for which \(N_i\) is the number of classes, \(N_i\) is the number of spectra in the \(i\)th class, \(\bar{x}_i\) is the class mean, and the \(\bar{x}\) is the global mean. The rank of \(R\) will be equal to the number of classes less one (e.g. \(N_c - 1\)), because a degree of freedom is lost by centering the spectra about the global mean and the product of two matrices can not exceed the minimum rank of the two multiplier matrices.\(^{66}\) The CVs are a basis set of orthogonal vectors that maximize the separations of the classes (i.e. maximize the distance among the means...
and minimize the distance of the spectra from their class means). Thus the principle of CVA is similar to PCA but, because the objective of CVA is to maximize the ratio of the between-group to within-group variance, a plot of the first two CVs displays the best two-dimensional representation of the class separation.

5.4.3 Factor Analysis

PCA yields variable loadings that are characteristic for the data matrix. The variable loadings are meaningful with respect to maximizing variances. For other applications it is useful to rotate these loadings in other directions that pertain to specific problems. Once the principal components are rotated, the technique is referred to as FA. Rotations are either oblique or orthogonal. The orthogonal rotations maintain the linear independence of the principal components and the basis. Oblique rotations remove the constraint of linear independence and therefore model more closely physical and chemical phenomena. These methods calculate a square matrix \( T \) of coefficients that rotate the components with a dimensionality of \( r \). For which \( r \) is the number of principal components. Typically, the column-space components or observation scores are rotated in the forward direction and the row-space components or variable loadings are rotated in the reverse direction using \( T^{-1} \). The rotation matrices can be computed by numerical optimization of a variety of objective functions or they can be rotated graphically until they resemble a target. For orthogonal rotation, the most popular objective function is Varimax.\(^{67}\) This rotation method seeks to increase the magnitude of the observation scores on a single component and reduce the scores magnitude on all other components.

Target transformation calculates a transformation matrix that rotates the row-space and column-space eigenvectors or components in directions that agree with a target vector. Typically, the targets are a set of properties that may correlate with the objects, and the transformation matrix is calculated by regression. These transformation matrices may be calculated using the eigenvectors from SVD (Equations 12 and 13),

\[
T = U^T X \tag{12}
\]

\[
\hat{X} = U T \tag{13}
\]

for which \( X \) is composed of columns of targets, \( T \) is the transformation matrix, and \( \hat{X} \) is the estimated target matrix. The loadings can be rotated by regressing the matrix of variable loadings \( V \) onto the target matrix \( T \) that has \( r \) rows and the number of columns equals the number of target vectors (Equation 14):

\[
\hat{Y} = VT(T^T T)^{-1} \tag{14}
\]

In some cases, it is advised to use the pseudo-inverse of \( T \), because the inner product of \( T \) may be ill-conditioned or singular. The factor variable loadings for the targets are estimated by \( \hat{Y} \).

5.5 Related Methods and Future Applications

5.5.1 Calibration

There are various methods to exploit the properties of eigenvectors to accomplish calibration. Calibration furnishes models that predict properties from data such as mass spectra. The most common use for calibration is to construct models that estimate the concentration of components in complex samples by their mass spectra.

Principal component regression (PCR) uses the observation scores for computing the regression model. The advantage of this approach is that for MS data in many cases \( D \) is underdetermined (i.e. more \( m/z \) measurements than spectra). Because the observation scores will equal the chemical rank, the number of variables are reduced and regression by inverse least squares becomes possible.

A related method uses SVD to calculate the pseudoinverse \( D^+ \). The SVD regression is computationally more efficient than PCR, but is mathematically equivalent. A very effective method for many problems is partial least squares (PLS). This calculates common column-space eigenvectors between the independent block (i.e. \( D \)) and dependent block (i.e. \( Y \)) of data. The PLS method was initially developed in the field of econometrics. Both PLS and PCA are described in a tutorial.\(^{68}\) PLS has been enhanced to handle multivariate or higher-order data.\(^{69}\)

Quantitative analysis of complex binary and tertiary biochemical mixtures analyzed with PyMS\(^{70}\) showed that, of the latent variable PCR and PLS methods, the best technique was PLS, a finding to be found generally by other studies.\(^{71,72}\)

5.5.2 Multivariate Curve Resolution

The same FA methods that were initially applied to peaks of GC/MS data have evolved so that they can be applied to the entire chromatographic runs. These methods start with a set of principal components. The components are rotated by a method known as alternating least squares (ALS). The key is to apply mathematical constraints such as non-negativity (no negative peaks) and unimodality (a spectrum will appear in only one peak of a chromatogram).

Curve resolution provides a means to enhance the spatial or depth resolution of ion measurements of surfaces or could be exploited to examine changes in electrospray mass spectra as a function of changing solvent conditions. Curve resolution will continue to exploit PCA and FA.
to detect impure chromatographic peaks and mathematically resolve the overlapping components.

EFA and window factor analysis (WFA) use the eigenvalues to model the change in concentrations of components in the data matrices. The eigenvalues can be combined to form initial concentration profiles that are regressed onto the data. The concentration profiles and extracted spectra are refined using ALS with constraints.

5.5.3 Multiway Analysis

The entire chromatographic mass spectral data matrix $D$ is only the beginning. If several chromatographic runs are used to characterize a chemical process or if multidimensional MS matrices of data are collected, a tensor or cube of data would be obtained. Using methods based on the Tucker model,$^{(73)}$ the higher-order sets of data can be decomposed into vectors or planes of principal components. A method related to the Tucker model is PARAFAC.

5.6 Reviews and Tutorials

Malinowski’s monograph is an excellent resource for PCA and FA.$^{(74)}$ Tutorials on FA and related methods can be found in the literature – the philosophical basis of PCA and FA,$^{(75)}$ EFA,$^{(76)}$ and target transform FA.$^{(77)}$ Multivariate curve resolution applied to chromatography with multichannel detection has been published as a tutorial$^{(78)}$ and reviewed specifically for GC/MS.$^{(79)}$ Tutorials of the multiway PCA method PARAFAC$^{(80)}$ and PLS$^{(68)}$ are also useful entry points into these methods. The text by Martens and Næs on multivariate calibration thoroughly describes PLS.$^{(81)}$

5.7 Acknowledgments

Tricia Buxton, Guoxiang Chen, and Aaron Urbas are thanked for their help with preparing this section. Thomas Isenhour and Kent Voorhees are thanked for their help with searching the literature. The introductory example data set was initially prepared by Peter Tandler.

6 ARTIFICIAL NEURAL NETWORKS

6.1 Summary

The availability of powerful desktop computers in conjunction with the development of several user-friendly packages that can simulate ANNs has led to the increase in adoption of these ‘intelligent’ systems by the analytical scientist for pattern recognition. The nature, properties and exploitation of ANNs with particular reference to MS is reviewed.

6.2 Introduction to Multivariate Data

Multivariate data consist of the results of observations of many different characters (variables) for a number of individuals (objects).$^{(82,83)}$ Each variable may be regarded as constituting a different dimension, such that if there are $n$ variables each object may be said to reside at a unique position in an abstract entity, referred to as $n$-dimensional hyperspace. In the case of MS, these variables are represented by the intensities of particular mass ions. This hyperspace is necessarily difficult to visualize, and the underlying theme of multivariate analysis (MVA) is thus simplification$^{(84)}$ or dimensionality reduction, which usually means that we want to summarize a large body of data by means of relatively few parameters, preferably the two or three that lend themselves to graphical display, with minimal loss of information.

6.3 Supervised Versus Unsupervised Learning

Conventionally the reduction of the multivariate data generated by MS$^{(85–87)}$ has normally been carried out using PCA.$^{(84,88–90)}$ the PCA technique is well-known for reducing the dimensionality of multivariate data while preserving most of the variance, and the principal component scores can easily be plotted and clusters in the data visualized.

Analyses of this type fall into the category of unsupervised learning (Figure 7a), in which the relevant multivariate algorithms seek clusters in the data.$^{(90)}$ Provided that the data set contains standards – of known origin and relevant to the analyses – it is evident that one can establish the closeness of any unknown samples to a standard, and thus effect the identification of the former. This technique is termed ‘operational fingerprinting’ by Meuzelaar et al.$^{(91)}$

Such methods, although in some sense quantitative, are better seen as qualitative as their chief purpose is merely to distinguish objects or populations. More recently, a variety of related but much more powerful methods, which are most often referred to within the framework of chemometrics, have been applied to supervised analysis of multivariate data (Figure 7b). In these methods, one seeks to relate the multivariate MS inputs to the concentrations of target determinants, i.e. to generate a quantitative analysis, essentially via suitable types of multidimensional curve fitting or linear regression analysis.$^{(83,92–96)}$ Although nonlinear versions of these techniques are increasingly available,$^{(97–103)}$ the usual implementations of these methods are linear in scope. However, a related approach to chemometrics, which is inherently nonlinear, is the use of ANNs.
ARTIFICIAL INTELLIGENCE AND EXPERT SYSTEMS IN MASS SPECTROMETRY

6.4 Biological Inspiration

ANNs are biologically inspired; they are composed of processing units that act in a manner that is analogous to the basic function of the biological neuron (Figure 8). In essence, the functionality of the biological neuron consists of receiving signals, or stimuli, from other cells at their synapses, processing this information, and deciding (usually on a threshold basis) whether or not to produce a response, that is passed onto other cells. In ANNs these neurons are replaced with very simple computational units which can take a numerical input and transform it (usually via summation) into an output. These processing units are then organized in a way that models the organization of the biological neural network, the brain.

Despite the rather superficial resemblance between the ANN and biological neural network, ANNs do exhibit a surprising number of the brain’s characteristics. For example, they learn from experience, generalize from previous examples to new ones, abstract essential characteristics from inputs containing irrelevant data, and make errors (although this is usually because of badly chosen training data). All these traits are considered more characteristic of human thought than of serial processing by computers. These systems offer the mass spectrometrist the capability of performing pattern recognition on very complex uninterpretable (at least to the naked eye) multivariate data.

For a MS analytical system, there are some mass spectra that have desired responses, which are known (i.e. the concentration of target determinands). These two types of data (the representation of the objects and their responses in the system) form pairs, which are usually called inputs and targets. The goal of supervised learning is to find a model or mapping that will correctly associate the inputs with the targets (Figure 7).

Thus the basic idea in these supervised learning neural network techniques is that there are minimally four...
datasets to be studied, as follows. The training data consist of (a) a matrix of \( s \) rows and \( n \) columns in which \( s \) is the number of objects and \( n \) the number of variables (these are the normalized ion intensities at a particular mass-to-charge ratio for MS), and (b) a second matrix of target data, again consisting of \( s \) rows and typically 1 or two columns, in which the columns represent the variable(s) whose value(s) it is desired to know (these are the result(s) wanted) and which for the training set have actually been determined by some existing, benchmark method. This variable may be the concentration of a target determinand, and is always paired with the patterns in the same row in (a). The test data also consist of two matrices, (c) and (d), corresponding to those in (a) and (b) above, but the test set contains different objects. As the name suggests, this second pair is used to test the accuracy of the system; alternatively they may be used to cross-validate the model. That is to say, after construction of the model using the training set (a, b) the test data (c) (these may be new spectra) are then passed through the calibration model so as to obtain the model’s prediction of results. These may then be compared with the known, expected responses (d).

6.5 Data Selection

As in all other data analysis techniques, these supervised learning methods are not immune to sensitivity to badly chosen initial data, and so good modelling practice must be adopted. Therefore, the exemplars for the training set must be carefully chosen; the adage is ‘garbage in – garbage out’. It is known that neural networks (and other supervised learning methods such as PLS) can over-fit data. For example, an over-trained neural network has usually learnt perfectly the stimulus patterns it has seen but cannot give accurate predictions for unseen stimuli, i.e. it is no longer able to generalize. For supervised learning methods accurately to learn and predict the concentrations of determinands in biological systems, or to identify new observations as being from something previously seen, the model must obviously be calibrated to the correct point. The reality is that in extension to normal chemometric practices detailed above the data should be split into three sets: (a) data used to calibrate the model; (b) data employed to cross-validate the model; and (c) spectra whose determinand concentration, or identities, were unknown and used to test the calibrated system. During calibration, the models would be interrogated with both the training and the cross-validation set and the error between the output seen and that expected calculated, thus allowing two calibration curves for the training and cross-validation sets to be drawn. When the error on the cross-validation data was lowest, the system will be deemed to have reached the best generalization point and then may be challenged with input stimuli whose determinand concentrations, or identities, are really unknown.

An alternative approach is to determine an acceptable error for the model, and construct ANN models that fit within this error. For many classification problems a relative root mean square error of calibration (RRMSEC) of 10% is usually sufficient (Equation 15):

\[
\text{RRMSEC} = \frac{\sum_{i=1}^{s} \sum_{j=1}^{p} (y_{ij} - \hat{y}_{ij})^2}{\sum_{i=1}^{s} \sum_{j=1}^{p} (y_{ij} - \bar{y}_{j})^2}
\]

for which RRMSEC is the relative root mean square standard error of calibration, \( \hat{y}_{ij} \) is the neural network output of unit \( j \) and training object \( I \), \( y_{ij} \) is the corresponding target value. There are \( p \) outputs for the neural network model and \( s \) training objects about the class mean \( \bar{y}_{j} \).

Many neural network models are often overly optimized and do not generalize well, even though monitoring sets or cross-validation are used. The caveat is that the prediction and training sets must be well designed and representative of the specific problem. With poorly designed training and prediction sets the neural networks will model hidden experimental factors that correlate with the target properties. A second problem occurs when the prediction set is used to configure the network – if the prediction set matches the training set too well the ANN model will overtrain, and if the prediction set is too dissimilar the network will undertrain.

Latin-partitioning is a useful experimental design tool for evaluating neural network models, the method constructs training and prediction set pairs for which each target object in the data is present once and only once in the prediction sets. The method randomly partitions the data so that each target pattern is represented in the sets with equal proportionality. This method is important because the composition of the prediction set is a major source of variation for evaluating neural network models and by including all objects in the prediction set it will not be biased.

For quantitative determinations it is also imperative that the objects fill the sample space. If a neural network is trained with samples in the concentration range from 0% to 50% it is unlikely to give accurate estimates for samples whose concentrations are greater than 50%; that is to say, the network is unable to extrapolate. Furthermore for the network to provide good interpolation it needs to be
trained with a number of samples covering the desired concentration range.\textsuperscript{111}

\subsection*{6.5.1 Sensitivity Analysis of Artificial Neural Network Models}

Sensitivity analysis may be used to probe ANN models and can lead to an understanding as to why they do not predict or generalize well. Furthermore, interpreting the sensitivities may lead to an understanding of causal relationships between input and output variables. Kowalski and Faber proposed methods on the quantitative measurement of sensitivities.\textsuperscript{112} Ebhart et al.\textsuperscript{113} proposed three comparable methods to calculate the mean square sensitivity, absolute value average sensitivity, and maximum sensitivity. Similarly, Howes and Crook\textsuperscript{114} studied the three types of input influence, namely general influence, specific influence, and potential influence, on the network output. Most of these studies considered the effects of weight matrix in multilayer perceptrons (MLPs) models. Choi and Choi\textsuperscript{115} defined the sensitivity of input perturbations as the ratio of output error to the standard deviation of each input perturbation, which involves complex weight calculations. Kovalishyn et al.\textsuperscript{116} have proposed several sensitivity measurements to be used with cascade-correlation networks (CCNs) for variable selection. The sensitivity was measured by connection weights, or the second derivative of the error function with respect to the neuron weight. It was shown in this paper, the sensitivities measured from their definition were not stable with the dynamic growth of the network, and also sensitive to addition of noise. In Ikonomopoulos’ study of importance of input variables with the wavelet adaptive neural network, the sensitivity of input variables was estimated by the ratio of the standard deviations of the prediction and the altered input.\textsuperscript{117} It was found that with this method, sensitivity measurements were highly correlated with the input perturbation. Sung derived the sensitivity coefficient matrix for a backpropagation (BP) neural network with two hidden layers.\textsuperscript{118} Other sensitivity analysis methods based on the input magnitude and functional measurements have also been proposed.\textsuperscript{119,120}

Because neural network models are fundamentally nonlinear, the sensitivity will depend on the input values from which they are calculated. Harrington et al.\textsuperscript{121} proposed using partial derivatives of the neural network output with respect to the input. They compare the sensitivity of the average input for each class with the average sensitivity of each class. This method provides a method for detecting input variables that are modeled by higher-ordered functions in the neural network model, and provides a quantitative measure of the input variables contribution for each target output. Weight vectors were not directly involved in the sensitivity measurement.

\section*{6.6 Cluster Analyses with Artificial Neural Networks}

These analyses fall into the category of unsupervised learning, in which the relevant multivariate algorithms seek clusters in the data.\textsuperscript{90} Recently there has been an interest in the use of neural computation methods, which can perform exploratory data analyses on multivariate data, the most commonly used are feature or self-organizing maps (SOMs) and auto-associative artificial neural networks (AAANNs).

\subsection*{6.6.1 Self-organizing Maps}

These provide an objective way of classifying data through self-organizing networks of artificial neurons.\textsuperscript{122–124} These neural networks are also referred to as Kohonen ANNs, after their inventor.\textsuperscript{125} The SOM algorithm is very powerful and is now extensively used for data mining, representation of multidimensional data and the analysis of relationships between variables.\textsuperscript{126}

The SOMs used to analyze mass spectra typically consist of a two-dimensional network of neurons arranged on a rectangular grid;\textsuperscript{127–129} although a variety of output arrays (Figure 9) and hence neighborhoods are possible.

Consider the situation where a square two-dimensional Kohonen output layer is used (Figure 9b). Each neuron

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{Figure9.png}
\caption{Commonly used SOM structures: (a) one-dimensional array, (b) two-dimensional rectangular network, (c) two-dimensional hexagonal network. The lines represent the neighborhoods.}
\end{figure}
Figure 10 A simplified SOM. Nodes in the two-dimensional Kohonen layer are interconnected with each other (only a few are shown in this figure), such that an activation node also tends to activate surrounding nodes (Figure 3). The mass spectral data are applied to the input layer which activates a node or group of neighboring nodes in the Kohonen layer (represented here as having $3 \times 3$ nodes).

is connected to its eight nearest neighbors on the grid. The neurons store a set of weights (a weight vector), each of which corresponds to one of the inputs in the data. (Figure 10 shows a diagrammatic representation of a SOM). Thus, for mass spectral data consisting of 150 quantitative ion intensity measurements at particular $m/z$ charges, each node stores 150 weights in its weight vector. Upon presentation of a mass spectrum (represented as a vector consisting of the 150 ion counts) to the network each neuron calculates its activation level. A node’s activation level is defined as Equation (16):

$$\sum_{i=0}^{n} (\text{weight}_i - \text{input}_i)^2$$

This is simply the Euclidean distance between the points represented by the weight vector and the input vector in $n$-dimensional space. Thus a node whose weight vector closely matches the input vector will have a small activation level, and a node whose weight vector is very different from the input vector will have a large activation level. The node in the network with the smallest activation level is deemed to be the winner for the current input vector.

During the training process the network is presented with each input pattern in turn, and all the nodes calculate their activation levels as described above. The winning node and some of the nodes around it are then allowed to adjust their weight vectors to match the current input vector more closely. The nodes included in the set, which are allowed to adjust their weights are said to belong to the neighborhood of the winner. The size of the winner’s neighborhood is varied throughout the training process. Initially all of the nodes in the network are included in the neighborhood of the winner but, as training proceeds, the size of the neighborhood is decreased linearly after each presentation of the complete training set (all the mass spectra being analyzed), until it includes only the winner itself. The amount by which the nodes in the neighborhood are allowed to adjust their weights is also reduced linearly throughout the training period.

The factor, which governs the size of the weight alterations is known as the learning rate and is represented by $\alpha$. The iterative adjustments to each item in the weight vector (where $\delta w$ is the change in the weight) are made in accordance with Equation (17):

$$\delta w_i = -\alpha(\text{weight}_i - \text{input}_i)$$

This is carried out for $i = 1$ to $i = n$, where in this case $n = 150$. The initial value for $\alpha$ is 1 and the final value is 0.

The effect of the learning rule (weight update algorithm) is to distribute the neurons evenly throughout the region of $n$-dimensional space populated by the training set. This effect is displayed in Figure 11, which shows the distribution of a square network over an evenly populated two-dimensional square input space. The neuron with the weight vector closest to a given input pattern will win for that pattern and for any other input patterns that it is closest to. Input patterns that allow the same node to win are then deemed to be in the same group, and when a map of their relationship is drawn a line encloses them. By training with networks of increasing size, a map with several levels of groups or contours can be drawn. However, these contours may sometimes cross which

![Increasing number of learning iterations (epochs)](image)

Figure 11 Representations of square networks distributed across an evenly distributed square input space.
appears to be due to failure of the SOM to converge to an even distribution of neurons over the input space.\(^ {130} \) Construction of these maps allows close examination of the relationships between the items in a training set.

A relatively recent paper by Belic and Gyergyek\(^ {131} \) compared several neural network methodologies for the recognition of MS data, based on simulated mass spectra samples and concluded that SOMs could be recommended for practical use in MS recognition. Somewhat earlier, however, Lohninger and Stancl\(^ {132} \) first showed that SOMs were better than \( k \)-nearest neighbor clustering for the discrimination of (real) mass spectra of steroids from eight distinct classes of chemical compounds. Goodacre et al. have also exploited SOMs successfully to carry out unsupervised learning on pyrolysis mass spectra, and hence the classification of canine \( P. \)\( \text{acnes} \) isolates,\(^ {127} \) \( P. \)\( \text{acnes} \) isolated from man,\(^ {133} \) and plant seeds.\(^ {128} \)

**6.6.2 Auto-associative Artificial Neural Networks**

AAANNs are a neural network-based method again for unsupervised feature extraction and were pioneered by Kramer.\(^ {134, 135} \) They consist of five layers containing processing nodes (neurons or units) made up of a layer of \( x \) input nodes, \( x \) output nodes (exactly the same as used in the input layer), and three hidden layers containing (in the example shown in Figure 12) 7, 3 and 7 nodes respectively; this may be represented as an \( x \)-7-3-7-\( x \) architecture. Adjacent layers of the network are fully interconnected, and the algorithm used to train these neural networks is the standard BP.\(^ {136, 138} \) As these neural networks are auto-associative in nature, that is to say, during training the input and output layer are presented with identical multivariate data, a key feature of these networks is the data compression in the middle (third) bottle-neck layer of three nodes. The second and fourth layers each consist of nodes that map and demap the multivariate data, allowing feature extraction in the bottle-neck layer. Moreover this is equivalent to nonlinear PCA.\(^ {134, 135} \) After training, each of the multivariate data used to train the AAANN is applied in turn to the input layer and the overall activation on the three nodes in the bottle-neck layer calculated. Plots of the activations of the nodes in the bottle-neck layer therefore allow clusters to be found in the data.

With reference to MS these AAANNs have only been applied to PyMS, to effect exploratory cluster analyses for the classification of plant seeds\(^ {128} \) and for the authentication of animal cell lines.\(^ {139} \) In the latter study this method of nonlinear PCA was particularly useful because the clusters observed were comparable with the groups obtained from the more conventional statistical approaches of hierarchical cluster analysis. This approach could detect the contamination of cell lines with low numbers of bacteria and fungi, and may plausibly be extended for the rapid detection of mycoplasma infection in animal cell lines.

Elsewhere, within spectroscopy, AAANNs have been used to reduce the dimensionality of the infrared (IR) spectra of polysaccharides and hence extract spectral features due to polysaccharides,\(^ {140} \) to detect plasmid instability using on-line measurements from an industrial fermentation producing a recombinant protein expressed by \( Escherichia \)\( \text{coli} \),\(^ {141} \) and for knowledge extraction in chemical process control.\(^ {142} \) An optimal associative memory (OAM) was developed for removing backgrounds from mid-IR spectra.\(^ {143, 144} \) The memory stores reference spectra and generates a best-fit reference spectrum when a sample IR scan is input. This method was extended to a fuzzy optimal associative memory (FOAM) by implementing fuzzy logic to near-IR spectra and was applied to calibration models of glucose in bovine plasma.\(^ {145} \)

**6.7 Supervised Analysis with Artificial Neural Networks**

As discussed above when the desired responses (targets) associated with each of the inputs (spectra) are known, the system is referred to as supervised. ANNs are very powerful at finding a mapping that will correctly associate mass spectra with known targets; these targets may be the identity of something, or be the quantitative amount of a substance. The two most exploited of the neural computational methods for these purposes are MLPs,
Figure 13 Binary encoding the five nodes in the output layer on a MLP or radial basis function trained to classify one of five substances i–v.

using standard BP of error, and radial basis function neural networks (RBFs).

In MLPs and RBFs that are to be trained for identification purposes the training data used to calibrate the model (as detailed above) consist of (a) a matrix of \( s \) rows and \( n \) columns in which \( s \) is the number of objects and \( n \) the number of variables, and (b) a second matrix, again consisting of \( s \) rows and the same number of columns as there are classes to be identified. For identification these \( s \) rows are binary encoded as shown in Figure 13; these are the result(s) wanted and for which the training set have actually been determined by classical identification methods, and are always paired with the patterns in the same row in (a). Once trained, new input data can be passed through these ANNs, and the identities read off easily because a tabular format is employed in the classification encoding. Alternatively, for quantification purposes the output node (or nodes) would encode the amount of the substance(s) (in a mixture) that had been analyzed.

The following texts and books are recommended introductory texts to ANNs:

104; 106; 108; 123; 136; 137; 146 – 154

The following section briefly describes the salient features of both MLPs and RBFs.

6.7.1 Multilayer Perceptrons

The structure of a typical MLP is shown in Figure 14(a) and consists of three layers: MS data as the input layer, connected to an output layer encoded for identification or quantification purposes, via a single hidden layer. Each of the input nodes are connected to the nodes of the hidden layer using abstract interconnections (connections or synapses). These connections each have an associated real value, termed the weight \( (w_i) \), that scales the input \( (i_i) \) passing through them, this also includes the bias \( (\vartheta) \), which also has a modifiable weight. Nodes sum the signals feeding to them (Net; Equation 18):

\[
Net = i_1w_1 + i_2w_2 + i_3w_3 + \ldots + i_nw_n
\]

\[
= \sum_{i=1}^{n} i_iw_i + \vartheta
\]

(Equation 18)

These signals (Out) are then passed to the output nodes which sums them and in turn squashes this summation by the above sigmoidal activation function; the product of this node is then fed to the outside world.

For the training of the MLP the algorithm used most often is standard BP. Briefly when the input is applied to the network, it is allowed to run until an output is produced at each output node. The differences between the actual and the desired output, taken over the entire training set are fed back through the network in

\[
Out = \frac{1}{(1 + \exp(-Net))}
\]

(Equation 19)
the reverse direction to signal flow (hence BP) modifying the weights as they go. This process is repeated until a suitable level of error is achieved.

One reason that MLPs are so attractive for the analysis of multivariate (spectral) data is that it has been shown mathematically that an MLP neural network consisting of only one hidden layer, with an arbitrarily large number of nodes, can learn any, arbitrary (and hence nonlinear) mapping of a continuous function to an arbitrary degree of accuracy.

Counter-propagation neural networks use a Kohonen hidden layer that is coupled to a Grossberg output layer. These networks are hybrid in that the output layer trains by supervised delta learning and the input is unsupervised. These networks were the early precursors to the radial basis function networks. Harrington and Pack modified the counterpropagation training algorithm so that both hidden and output layers were concomitantly optimized.

Training MLP networks is a very inefficient process, because all processing units are adjusted simultaneously. In addition, the number of hidden units and layers must be configured before training. The CCN developed by Fahlman and Lebiere overcomes these limitations. They add hidden units as needed to reduce the calibration error. The CCN only adjusts a single processing unit or neuron at a time, and therefore trains faster than BP networks.

The problem with the perceptron model is that typically if the spectra form clusters in the data space, there are an infinite set of weight vectors orientations that will furnish zero calibration errors regardless of the dimensionality of the input data. A solution to this problem is to constrain the perceptron model. Temperature constraints that originated with the minimal neural network (MNN), were implemented in BP neural networks with a single global temperature, and local temperature constraints for individual perceptrons in the CCNs. The temperature relates to the thermodynamic temperature employed in other methods such as simulated annealing (reference), and controls the magnitude of the weight vector length (i.e., in Equation 3). The networks are trained so that the maximum of the first derivative of the objective function (e.g., error in BP and covariance in CCN) is maximized with respect to temperature. This constraint ensures that the derivative of the weight vector is large, to facilitate the training rate and the output of the perceptron remains continuous, which improves the reproducibility and the generalization capability of the networks.

6.7.2 Radial Basis Functions

By contrast, RBFs are hybrid neural networks encompassing both unsupervised and supervised learning. They are also typically three-layer neural networks and, in essence, the sigmoidal squashing function is replaced by nonlinear (often either Gaussian or Mexican hat) basis functions or kernels (Figure 14b). The kernel is the function that determines the output of each node in the hidden layer when an input pattern is applied to it. This output is simply a function of the Euclidean distance from the kernel center to the presented input pattern in the multidimensional space, and each node in the hidden layer only produces an output when the input applied is within its receptive field; if the input is beyond this receptive field the output is 0. This receptive field can be chosen and is radially symmetric around the kernel center. Between them the receptive fields cover the entire region of the input space in which a multivariate input pattern may occur; a diagrammatic representation of this is given in Figure 15, where a two-dimensional input is mapped by eight radially symmetric basis functions. This is a fundamentally different approach from the MLP, in which each hidden node represents a nonlinear hyperplanar decision boundary bisecting the input space (Figure 15a). Thus RBFs have the advantage over gradient descent MLPs in that they have the ability to learn any arbitrary nonlinear mapping of a discontinuous function to an arbitrary degree of accuracy.

The outputs of the RBF nodes in the hidden layer are then fed forward via weighted connections to the nodes in the output layer in a similar fashion to the MLP, and each output node calculates a weighted sum of the outputs from the nonlinear transfer from the kernels in the hidden layer. The only difference is that the output nodes of an RBF are normally linear, whilst those of the MLP more typically employ a sigmoidal or logistic (nonlinear) squashing function.

Thus in the RBF training proceeds in two stages. Stage 1 involves unsupervised clustering of the input data, typically using the K-means clustering algorithm to divide the high-dimensional input data into clusters. Next, kernel centers are placed at the mean of each cluster of data points. The use of K-means is particularly convenient because it positions the kernels relative to the density of the input data points. Next the receptive field is determined by the nearest neighbor heuristic where (the radius of kernel is set to the Euclidean distance between the vector determining the centre for the jth RBF) and its nearest neighbor (k), and an overlap constant (Overlap) is used (Equation 20):

\[ r_j = \text{Overlap} \times \min(\|w_j - w_k\|) \]  

where \( \| \cdots \| \) denotes a vector norm, or Euclidean distance. The overlap that often gives best results is where the edge of the radius of one kernel is at the centre of its nearest neighbor.
regression method.\textsuperscript{(101)} Wan and Harrington used SVD regression and reported a self-configuring RBF network that optimizes the number of kernel functions.\textsuperscript{(175)}

6.8 Applications of Artificial Neural Networks to Pyrolysis Mass Spectrometry

PyMS involves the thermal degradation of nonvolatile complex molecules (such as bacteria) in a vacuum causing their cleavage to smaller, volatile fragments, separable by a mass spectrometer on the basis of their $m/z$.\textsuperscript{(91)} The PyMS method allows the (bio-)chemically-based discrimination of microbial cells (and other organic material) and produces complex biochemical fingerprints (i.e. pyrolysis mass spectra) which are distinct for different bacteria. It is the automation of the instrumentation and ease of use that has lead to the widespread exploitation of PyMS as a taxonomic tool for whole-organism fingerprinting.\textsuperscript{(86,176)} The analytically useful multivariate data (Figure 16) are typically constituted by a set of 150 normalized intensities versus $m/z$ in the range 51 to 200,

The output from nodes in the hidden layer is dependent on the shape of the basis function and the one used was that of the Gaussian. Thus this value ($R_j$) for node $j$ when given the $i$th input vector ($i_i$) can be calculated by (Equation 21):

$$R_j(i_i) = e^{-r_j/\sigma_j^2}$$

Stage 2 involves supervised learning using simple linear regression. The inputs are the output values for all $n$ basis functions ($R_l - R_n$) for all the training input patterns to that layer ($i_l - i_n$), and the outputs are identities binary encoded as shown in Figure 13. More recently, Walczak and Massart have used PLS as the linear

![Figure 15](image1)

**Figure 15** (a) Typical decision boundary for a classification problem created between two data classes by a MLP with two nodes in the hidden layer, for two input nodes. Each hidden node represents a nonlinear hyperplanar boundary and the node(s) in the output layer interpolate this to form a decision boundary. (b) The same classification problem modeled by eight radially symmetric basis functions. The width of each kernel function (referred to as its receptive field) is determined by the local density distribution of training examples.

![Figure 16](image2)

**Figure 16** Pyrolysis mass spectra: (a) the bacterium *Bacillus cereus* DSM 31; (b) the simple (bio)chemical caffeine.
and these are applied to the nodes on the input layers of ANNs.

The first demonstration of the ability of ANNs to discriminate between biological samples using their pyrolysis mass spectra was for the qualitative assessment of the adulteration of extra virgin olive oils with various seed oils(177,178) in this study, which was performed double-blind, neural networks were trained with the spectra from 12 virgin olive oils, coded ‘1’ at the output node, and with the spectra from 12 adulterated oils, which were coded ‘0’. All oils in the test were correctly identified; in a typical run, the virgins were assessed with a code of 0.99976 ± 0.000146 (range 0.99954 – 1.00016) and the adulterated olive oils in the test set with a code of 0.001079 ± 0.002838 (range 0.00026 – 0.01009). This permitted their rapid and precise assessment, a task which previously was labour intensive and very difficult. It was most significant that the traditional unsupervised MVA of PCA, DFA and HCA failed to separate the oils according to their virginity or otherwise, but rather discriminated them on the basis of their cultivar (that is to say, the biggest difference in the mass spectra was due to the type of olive tree that the fruit came from, rather than the adulterant).

The use of PyMS with MLPs for the analysis of foodstuffs is becoming widespread(179) and has been investigated for identifying the geographical origin of olive oils,(180) for the characterization of cocoa butters(181,182) and milk,(183,184) classification of pork backfat(185) and European wines,(186) for differentiating between industrially made vinegar ‘Aceto Balsamico di Modena’ and traditionally produced vinegar ‘Aceto Balsamico Tradizionale di Modena e di Reggio Emilia’,(187) for detecting the adulteration of orange juice,(188) and for detecting caffeine in coffee, tea and cola drinks.(189)

Several studies have also shown that this combination of PyMS and MLPs are also very effective for the rapid identification of a variety of bacterial strains of industrial, clinical and veterinary importance.(87,190) For example, this approach has allowed the propionibacteria isolated from dogs to be correctly identified as human Propionibacterium acnes,(127) for detecting Escherichia coli isolates which produced verocytotoxins,(191) for distinguishing between Mycobacterium tuberculosis and M. bovis,(192) and for identifying streptomycetes recovered from soil,(193–195) oral abscess bacteria,(196) and fungi belonging to the genus Penicillium which were associated with cheese.(197) An example of the highly discriminatory nature of MLPs is that one can even use them to differentiate between methicillin-susceptible and methicillin-resistant Staphylococcus aureus,(198) the relevant difference is an alteration in a single penicillin-binding protein.(199,200) Similarly, MLPs can be used to discriminate the physiological difference between sporulated and vegetative Bacillus species,(201) and differentiating the verocytotoxin production status in Escherichia coli.(191)

RBF have been rather less widely applied to the analysis of mass spectral data. Kang et al.(202,203) have exploited RBFs to detect physiological changes in industrial fermentations of Streptomyces species, whereas Goodacre et al.(204) have used RBFs for the identification of common infectious agents associated with urinary tract infection from their MS, IR, and Raman spectra.

An analytical expression for the derivatives of the entropy function for MNNs was derived.(205) This expression was implemented for classifying pyrolysis MS/MS data and the results were compared to those obtained from a BP/ANN.(206) The MNNs differ from BP/ANNs in that they use localized processing and build classification trees with branches composed of multiple processing units. A global entropy minimization may be achieved at a branch by combining the processing logic using principles from fuzzy set theory. Weight vectors are adjusted using an angular coordinate system and gradients of the fuzzy entropy function. The branches are optimal with respect to fuzziness and can accommodate nonlinearly separable or ill-conditioned data. The most significant advantage of the MNNs is that relations among the training data and the mechanism of inference may be directly observed; thus rule-based classification trees have been constructed from the mass spectral daughter ions to discriminate between diesel smoke, dry yeast, Escherichia coli, MS-2 coliphage, grass pollen, Bacillus subtilis, fog oil, wood smoke, aldolase and Bacillus globigii.(206)

6.8.1 Classification and Qualitative Analysis of Mass Spectra

ANNs may be used to construct classification models from mass spectra. Once the classification models are built they may be used to rapidly screen large collections of mass spectra. The earliest application of perceptron models was applied to substructure recognition from mass spectra.(207) MLPs were first employed for recognizing functional groups from large collections of mass spectra by Curry and Rumelhart.(208) Werther et al.(209) demonstrated that classifiers based on RBF were better at recognizing functional groups than soft independent models for class analogies (SIMCA210), K-nearest neighbors,(211) and linear discriminant analysis(212) from mass spectra.209) The combination of separation stages to mass spectrometers, such as chromatographic and electrophoretic, furnishes large collections of mass spectra. A fuzzy rule-building expert system (FuRES) was applied to screening GC/MS data of plastic recycling products.(213) The ES was capable
of classifying each mass spectral scan of the chromatographic run by degree of unsaturation (i.e. alkane, alkene, and diene) and furnished a separate chromatogram for each of the three classes. A FuRES has also been used to classify pyrolysis mass spectra and IR spectra.

Temperature-constrained cascade correlation networks (TCCCNs) were applied to the screening of GC/MS pesticide data. Substructures and toxicity ANN models were built for organophosphorus pesticides and applied to screening GC/MS data. The TCCCN was applied to recognizing substructures of carboxamides pesticides, and reported the Latin-partition method for evaluating ANN models.

### 6.8.2 Quantitative Analysis with Artificial Neural Networks

All the above studies have been classification problems but perhaps the most significant application of ANNs to the analysis of MS data is to gain accurate and precise quantitative information about the chemical constituents of microbial samples. For example, it has been shown that it is possible using this method to measure the concentrations of binary and tertiary mixtures of cells of the bacteria Bacillus subtilis, Escherichia coli, and Staphylococcus aureus. With regard to biotechnology, the combination of PyMS and ANNs can be exploited to quantify the amount of mammalian cytochrome b5 expressed in Escherichia coli, and to measure the level of metabolites in fermentor broths. In related studies Penicillium chrysogenum fermentation broths were analyzed quantitatively for penicillins using PyMS and ANNs, and this approach has also been used to monitor Gibberella fujikuroi fermentations producing gibberellic acid and quantify the level of clavulanic acid produced by Streptomyces clavuligerus, and to quantify the expression of the heterologous protein α2-interferon in Escherichia coli. These and related chemometric approaches have been extended to work with a variety of high dimensional spectroscopic methods, including those based on IR, Raman, dielectrics, and flow cytometric measurements.

### 6.8.3 Instrument Reproducibility

For MS to be used for the routine identification of microorganisms new (spectral) fingerprints must be able to be compared to those previously collected. However, the major problem with most analytical instruments is that long-term reproducibility is poor and interlaboratory reproducibility abysmal, and so the biochemical or genetic fingerprints of the same material analyzed at two different times are different. Because of the uncertainties over the long-term reproducibility of the PyMS system (defined as over 30 days), PyMS has really been limited within clinical microbiology to the typing of short-term outbreaks where all micro-organisms are analyzed in a single batch.

After tuning the instrument, to correct for drift one would need to analyze the same standards at the two different times and use some sort of mathematical correction method. This could simply be subtracting the amount of drift from new spectra collected; however, this assumes that the drift is uniform (linear) with time, which is obviously not the case. This method also relies on the variables (characters) being void of noise, which is also not the case. An alternative method would be to transform the spectra to look like the spectra of the same material previously collected using a method that was (a) robust to noisy data and (b) able to perform nonlinear mappings. ANNs carry out nonlinear mappings, while being able to map the linearities, and are purported to be robust to noisy data. These mathematical methods are therefore ideally suited to be exploited for the correction of mass spectral drift.

Goodacre and Kell have found that neural networks can be used successfully to correct for instrumental drift; identical materials were analyzed by PyMS at dates from 4 to 20 months apart, but neural network models produced at earlier times could not be used to give accurate estimates of determinand concentrations or bacterial identities. Calibration samples common to the two datasets were run at the two times, and ANNs set-up in which the inputs were the 150 new calibration masses and the outputs were the 150 calibration masses from the old spectra. Such associative nets could thus be used as signal-processing elements to effect the transformation of data acquired one day to those that would have been acquired on a later date. A further study has shown that one can also affect calibration transfer between laboratories using this approach. These results show clearly that for the first time PyMS can be used to acquire spectra which could be compared to those previously collected and held in a database. It should seem obvious that this approach is not limited solely to PyMS but is generally applicable to any analytical tool which is prone to instrumental drift (which cannot be compensated for by tuning).

### 6.9 Concluding Remarks

Within MS the move from a stare-and-compare approach to the analysis of highly dimensional multivariate data necessitates the use of chemometrics; particularly when quantitative information is sought from biological systems. The application of ANNs for quantitative and qualitative analyses is becoming more accepted within MS, especially because these neural computational methods clearly present themselves as extremely powerful and valuable tools for the analysis of complex data.
7 OPTIMIZATION TECHNIQUES IN MASS SPECTROMETRY

7.1 Introduction

Parameter optimization is often required in MS. It can be employed in the design of the instrument, tuning of conditions during operation, or calibration of mass scales in data analysis. Good sources of information on general optimization techniques are readily available.\(^{(230-235)}\) Therefore, a specific example is provided, illustrating how optimization is advancing MS capability. This example is the application of simplex optimization to mass calibration in TOF instruments.

The simplex method is one of the most popular of several mathematical techniques for optimizing multivariate systems. Developed in 1947, it is composed of successive tests and variation of independent parameters until the system is determined to be unbounded or optimized.\(^{(234)}\) Whereas the original method used a graphical representation, current methods rely on high-speed computing. The advances in computers allow the determination of optimal conditions in complicated systems involving a large number of independent parameters.

7.2 Time-of-flight Mass Spectroscopy Mass Calibration

Because of its simplicity and unlimited mass range, TOF instrumentation is particularly well-suited for the analysis of MALDI and electrospray-generated macromolecular ions. Recent advances in TOF technology have facilitated the attainment of high resolution in MALDI/TOF experiments,\(^{(236-239)}\) but the method's utility critically depends on its ability to measure ion masses accurately. An ion's flight time can be expressed as an exact function of its mass if information about its formation time, location, and initial velocity is available. Most often, this relationship is expressed to some level of approximation. To zeroth order, the TOF is given by Equation (22):

\[
\text{TOF} = k \times \text{mass}^{1/2} \tag{22}
\]

This is accurate only when ions are formed with zero initial velocity. Non-zero initial velocities introduce significant complications in the relationship between TOF and mass.

It is currently popular to express TOF as a multiterm polynomial function of mass.\(^{(240-242)}\) In this expansion the mass\(^{1/2}\) term is a dominant contributor, but additional terms are needed to produce accurate results. An infinite series is needed to reach arbitrary accuracy. In the polynomial curve-fitting approach, mass spectra of a variety of known calibrant samples are recorded, ion flight times are measured and the coefficients in the polynomial relating TOF to mass are derived using a least-squares minimization routine. When other samples of known mass are introduced into the instrument and their masses are derived using the polynomial relationship, mass accuracies in the parts per million realm have been demonstrated.\(^{(243)}\) Nevertheless, to achieve high-quality results with this method, it is necessary that the masses to be measured are near those of calibrants and it is best if they are bracketed by the latter. Attempts to extrapolate the mass calibration over a range that extends beyond that of the calibrants generally leads to poor results.

As an alternative to fitting TOF to an arbitrary polynomial function of mass, it is possible to use elementary physics to calculate the flight times of ions based on instrumental voltages, distances and other operating parameters. Besides not using arbitrary parameters, this approach incorporates the correct physical relationship between TOF and mass, and thus it should extrapolate more accurately into mass regions that are far from the calibrants. Although the merits of this approach are easy to envisage, the stumbling block to its use may be equivalently obvious. For ions initiating their trajectories in a TOF instrument with nonzero velocities, being accelerated in more than one field, drifting in a field-free region and, possibly being postaccelerated or decelerated, the relationship between TOF and mass contains a number of parameters whose exact values are not known well enough to provide the basis for an accurate mass calibration equation. For example, suppose that a singly charged lysozyme ion having a mass of 14 306 Da is accelerated to 20 keV total energy and drifts through a 1.00 m long field-free flight tube. The overall flight time is calculated to be 67 147.2 ns. An error in the high voltage of 10 V leads to a flight time shift of 15 ns. Likewise, an error in the drift tube length of 0.3 mm corresponds to a time shift of 18 ns. These numbers are equivalent to mass errors of 6.5 and 7.8 Da or 460 and 550 parts per million, respectively. Fortunately, accurate values for these imprecisely known instrument parameters can be derived through a simplex optimization procedure. This leads to both a mass calibration equation and a computationally accurate description of the instrument.

7.2.1 Use of the Simplex Algorithm

The minimization used in the simplex algorithm involves computing residual errors between an array of experimental and calculated flight times. The algorithm reiteratively optimizes the instrument parameters in order to minimize the difference between experimental flight times and those calculated using values of the instrument parameters. Any residual error function may be used in the minimization routine. For example, the sum of the squares of differences between experimental and calculated flight times has been used. Two of the input parameters needed by the Simplex algorithm are the characteristic length vector and the fit tolerance. Vector components are typically
matched to measurement uncertainties. The fit tolerance represents the desired conditions for termination of the optimization and is based on expected error between experimental and optimized calculations. Too small a value increases the iterative requirements of the calculation; too large a number causes the simplex navigation to terminate before a minimum is found.

The Simplex calculation constrains ion behavior to physically meaningful values as it is based on exact electrostatic equations. The significance of this can best be demonstrated through direct comparison with the curve-fitting approach to mass calibration. Theoretical flight times for 101 ions having masses between 100 and 1100 Da are initially computed using the exact electrostatic TOF expression. When the resulting flight times are fitted to an optimized three- or five-term polynomial function of mass, the residual errors are rather small, as displayed by the curves in Figure 17. Note that the scale of this graph is rather expanded. However, when the Simplex algorithm is employed for the same purpose, the calibration is seen to be noticeably improved. Although curve-fitting with an \( n \)-term polynomial exactly matches the theoretical data at the \( n \) points, discrepancies can be noted between these points. Furthermore the exact electrostatic calculations and the fitted polynomial diverge significantly at masses on the low and high ends of the calibration range. The quality of results obtained by curve-fitting does vary depending on the polynomial function form and in some cases can match that attained by Simplex. However, the general trends just noted are still observed.

An alternative way to compare the capabilities of Simplex-based mass calibration with the curve-fitting approach is to examine experimental data. A particularly interesting case involves a sample containing a mixture of alkylthioate-coated gold nanoparticles. The challenging aspect of this calibration problem is that gold nanoparticles are laser-desorbed and ionized without being incorporated into a matrix. Consequently, the resulting ions have a velocity distribution that is not characteristic of MALDI ions. In fact, gold nanoparticle ions have lower desorption velocities than their MALDI counterparts. Unfortunately, in the 10–20 kDa mass range, the most familiar mass calibration standards are MALDI-generated protein ions. Thus, an inherent incompatibility between sample and calibrants exists.

To deal with this, the parameters chosen for simplex optimization must be carefully chosen. In general, the best ones to optimize are those that are subject to the largest measurement error. Extraction voltage, the ion drawout pulse delay, and the length of the flight tube are all obvious choices. Optimization of this collection of parameters normally yields an accurate mass calibration for a mixture of peptides for which a typical initial ion velocity is 600 m s\(^{-1}\). However, for the gold sample, the Simplex optimization would not converge when ions were assigned this initial velocity. If the initial gold nanoparticle ion velocity is changed to 100 m s\(^{-1}\), the algorithm does converge, leading to RMS mass errors for about 30 ion peaks of 0.24 Da. This corresponds to 17 ppm error, which is respectable considering the velocity differences between MALDI-generated protein ions and gold ions. It is noteworthy that in this example, the Simplex algorithm provided more than just a means to perform mass calibration. It also yielded information about the average velocity with which the nanoparticles desorbed.

### 7.2.2 Mass Calibration Extrapolation

As noted above, calibration of most mass spectra is performed by surrounding the peaks of interest with a good set of known standards. It may seem unreasonable to expect a calibration method to remain accurate in mass regions extrapolated beyond the range of the calibrants. However, this is one of the virtues of the simplex approach. Six peaks in the gold nanoparticle mass spectrum were used to calibrate the spectrum. As displayed in Figure 18, a five-term polynomial curve fit established an acceptable relationship between masses and flight times for ions in the 13–14 kDa range. The simplex approach performed comparably well within this range. However, at masses below 13 kDa or above 14 kDa,
the high-order polynomial curve clearly changes slope and errors relative to the exact TOF calibration and the more realistic Simplex curve increase dramatically.

7.2.3 Conclusions

In summary, a simplex approach to calibrate MALDI/TOF mass spectra appears to be both robust and easily executed. It yields results that are comparable to those obtained with polynomial curve fitting for routine applications, and it excels under more difficult situations such as when samples and calibrants are fundamentally different, when calibrant peaks are incorrectly assigned, or when the mass range of interest must be extended beyond that of the calibrants. It should therefore be of utility in a wide variety of applications.

The atmospheric pressure ionization (API) techniques serve to transform neutral analytes into ionic species that may then be analyzed by mass spectrometry (MS). Ionization takes place under ambient pressure (~1 atm), and formed ions are subsequently directed into the low-pressure regions of the mass spectrometer for mass analysis. The API techniques have offered notable successes in enabling ionization of nonvolatile compounds contained in solution that are not amenable to “classical” mass spectrometric ionization techniques such as electron ionization and conventional chemical ionization. Under favorable API conditions, neutral analytes may be converted to ionic forms in extremely high efficiencies approaching 100%. Fundamental aspects and applications of the two most widely used API techniques, atmospheric pressure chemical ionization (APCI) and electrospray ionization (ESI), are discussed at length in this article.

APCI is a process by which initially dissolved solutes are ionized, after desolvation, through gas-phase ion–molecule reactions at atmospheric pressure. The resulting ions are then mass analyzed in an appropriate mass spectrometer. APCI generally utilizes continuous introduction of liquid samples at flow rates of 0.2–2 mL min⁻¹, and the technique is often used to interface liquid chromatography (LC) with MS. APCI can accommodate a wide range of solvents and solutes, and is one of the most widely applicable methods for the ionization of dissolved analytes. Molecular or quasi-molecular ions (e.g., M⁺, M⁻, [M + H]⁺, and [M − H]⁻) as well as adduct ions are typically formed in APCI. Generally, there is only slight to moderate fragmentation. To some extent, the degree of fragmentation can be adjusted, and the type of molecular or quasi-molecular ion can be altered by varying the ionization conditions. APCI can be divided into three general steps: nebulization/desolvation, ionization, and extraction. Each of these steps will be discussed in more detail below.

API was first developed in the early 1970s. Since then, extensive reviews have appeared on various API methods. The number of publications on APCI has increased steadily through the 1990s. The range of applicability of atmospheric pressure chemical ionization/mass spectrometry (APCI/MS) lies between that of gas chromatography/mass spectrometry (GC/MS) and electrospray ionization/mass spectrometry (ESI/MS). GC/MS is generally applicable to relatively low-boiling, thermally stable compounds with fairly low polarities and low molecular weights. On the other end of the spectrum, ESI/MS typically produces high signals for compounds, including large molecules, that exist in ionic forms in solution. APCI is applicable to all compounds between these two groups: slightly polar to highly polar with intermediate sizes and a broad range of boiling points. Furthermore, thermally labile compounds are generally amenable to APCI, except for a few highly unstable species. Figure 1 presents a qualitative depiction of the useful polarity ranges for various MS sample introduction methods.

The two major requirements for APCI are that a compound be soluble in a solvent and the compound must undergo some gas-phase reaction resulting in ionization. Because APCI can utilize most solvents and because ionization reactions can be adjusted by altering the conditions, APCI is widely applicable to most analytes. The major application of APCI is in interfacing LC with MS. Liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry (LC/APCI/MS) analyses
have been reported for environmental samples (pesticides, polycyclic aromatic hydrocarbons (PAHs), etc.), for agricultural and food samples (pesticides, vitamins, pigments, flavorings, fats, etc.) and for biomedical samples (drugs and metabolites, steroids, biomolecules, etc.), along with other applications.

The remainder of this article will detail the design, principles, and function of APCI interfaces. Practical considerations for the use of APCI will also be discussed, and examples of actual applications will be presented. These examples will illustrate experimental conditions used for the ionization of various compounds, and will indicate the capabilities and limitations of APCI.

1.1 Atmospheric Pressure Chemical Ionization Design and Function

APCI involves three primary steps: conversion of the analyte to a gas-phase species (nebulization and desolvation); ionization of the analyte through gas-phase ion–molecule reactions at atmospheric pressure; and extraction of the ions into the mass spectrometer with simultaneous exclusion of most of the nonionized species.

In some cases, the sample is already in the gas phase, and conversion is not necessary. Examples include direct sampling of atmospheric gases and the introduction of gas chromatographic effluents into the APCI source. Despite the utility of these applications, APCI has arisen primarily as a means of interfacing high-performance liquid chromatography (HPLC) to MS. These two methods are inherently incompatible due to the high density of liquids used in HPLC compared to the low-density vacuum required for MS. Therefore, a suitable interface is needed to ionize analytes and to eliminate the high volume of solvent molecules present. Efforts to interface HPLC with MS date to around the early 1980s, when moving-belt interfaces and direct liquid introduction were first developed. Although these devices succeeded in producing mass spectra from HPLC effluents, they were not practical. A number of devices were designed subsequently that relied on nebulization of the liquid followed by desolvation and ionization processes. These devices include thermospray, electrospay, particle beam, and APCI. Today, APCI and electrospay predominate the interfaces used for the introduction of liquid samples into mass spectrometers. A schematic of an APCI interface is presented in Figure 2. The details of each section of this interface will be discussed below.

1.1.1 Nebulization

The first step in APCI is nebulization of the liquid. In this step, the liquid is converted to small droplets, generally through interaction with a high-velocity gas with simultaneous heating. By breaking the liquid into small droplets and providing sufficient heat, the liquid sample is converted almost entirely into gas-phase species. A typical design for an APCI nebulizer consists of a fused silica capillary containing the liquid flow surrounded by a concentric, high-velocity flow of a nebulizing gas. In addition, a sheath gas surrounding the nebulizer may be utilized. Typically nitrogen is used as the nebulizer gas. For the interface in Figure 2, the nebulizer manifold is heated to 500–700 °C, with a maximum temperature of 1000 °C. Although these temperatures may seem high enough to cause significant thermal decomposition of analytes, the bulk of the energy is consumed in vaporization of the solvent. The actual temperature experienced by an analyte molecule is therefore significantly lower, and thermal degradation is generally not significant. Operation of the interface is compatible with common reversed-phase HPLC solvents, such as methanol, acetonitrile, and water. More discussion on solvent systems will be given in section 1.2.1.

The APCI nebulizer is quite similar to the design of thermospray nebulizers, which rely strictly on heating to induce vaporization of solvent and analytes usually in the presence of a volatile buffer additive. However, in thermospray, ionization of the analyte typically proceeds via interaction with the buffer salt and requires no supplemental electron process (such as a corona discharge as used in APCI).

1.1.2 Ionization

Following nebulization, any remaining condensed-phase droplets are evaporated in the heated region just after the nebulizer. Subsequent to this desolvation region is where the ionization process occurs. Ionization is
initiated by a corona discharge, although early instrument designs relied on a radioactive β-particle source instead of a corona discharge.\(^1,2,15\) The corona discharge is produced by a needle held at high voltage within the gas stream. The high potential between the needle and the sampling cone results in the emission of electrons that are accelerated in the field and initiate a gas discharge. For nitrogen, which is the most commonly used nebulizer gas, the discharge results in the following initial ionization processes (Equations 1–6) in the presence of water:\(^5\)

\[
\begin{align*}
N_2 + e & \rightarrow N_2^{\ddagger \ddagger} + 2e \quad (1) \\
N_2^{\ddagger \ddagger} + 2N_2 & \rightarrow N_4^{\ddagger \ddagger} + N_2 \quad (2) \\
N_4^{\ddagger \ddagger} + H_2O & \rightarrow H_2O^{\ddagger \ddagger} + 2N_2 \quad (3) \\
H_2O^{\ddagger \ddagger} + H_2O & \rightarrow H_3O^+ + HO^* \quad (4) \\
H_3O^+ + H_2O + N_2 & \rightarrow H^+(H_2O)_2 + N_2 \quad (5) \\
H^+(H_2O)_{n-1} + H_2O + N_2 & \rightarrow H^+(H_2O)_n + N_2 \quad (6)
\end{align*}
\]

In addition, species such as \(N_4^{\ddagger \ddagger}\) and \(N_3^{\ddagger \ddagger}\) are formed, and in the presence of oxygen, \(O_2^{\ddagger \ddagger}\) and various nitrogen oxide ions are also formed.\(^5\) The exact nature of the ions formed is dependent on the gaseous species present. In fact, addition of reagents to the liquid phase or nebulizer gas can be used to alter the ions present. This topic will be discussed in more detail below.

The ion–molecule reactions observed in APCI are in many ways similar to those observed for chemical ionization. However, because chemical ionization is conducted at much lower pressures (e.g. \(\sim 10^{-3}\) Torr), the reaction products are typically governed by kinetics, i.e. the most rapidly formed products are observed in highest abundances. In contrast, the APCI process generally results in the formation of the most thermodynamically stable product. Because APCI is carried out at atmospheric pressure, numerous gas-phase collisions occur, allowing equilibrium to be approached. The time allowed for equilibration can be altered by adjusting the position of the corona discharge needle. When the corona is relatively far from the first sampling aperture, equilibrium is generally achieved. If the corona is initiated close to the sampling aperture, much less time is available for equilibration, and kinetic products tend to predominate. This phenomenon occurs because the gas rapidly expands into the low-pressure region behind the sampling aperture. Once expansion occurs, collisions are minimized and only unimolecular decompositions take place, so that equilibration can no longer occur. Therefore, the closer the discharge is to the sampling aperture, the less time is available at atmospheric pressure to obtain equilibrium. The profile of ions observed for a corona discharge in nitrogen at different distances from the sampling aperture is illustrated in Figure 3. A clear change in the predominant ions is observed, corresponding to a shift from kinetic products to thermodynamic products.

With the continuous presence of solvent- or nebulizer-gas-reactive ions in the source region, introduction of an analyte leads to ion–molecule reactions between the analyte and the ions present. The widespread applicability of APCI to many compounds is the result of the ability to find reaction conditions that produce
Figure 3  Ions observed for nitrogen in a corona discharge with the corona needle held at different distances from the sampling aperture: (a) 0.5 mm, ions are not thermally equilibrated; (b) 4 mm, ions are thermally equilibrated. (Reproduced with permission from Carroll et al.5)

Data from van Baar.16
The GPAs for several compounds are listed in Table 2.

Unlike low-pressure chemical ionization (e.g. \( \sim 10^{-3} \)Torr), in APCI the internal energy resulting from a chemical reaction can be dissipated by collisions with neutral species present at atmospheric pressure, such as \( \text{N}_2 \). In general, the chemical ionization processes occurring in APCI are somewhat selective. Therefore, depending upon the reagent ions present in the source, a molecule may or may not be ionized. This property may be either a potential advantage or perhaps a disadvantage. The advantage comes in the possibility of selectively ionizing compounds of interest but not ionizing other species. The disadvantage is that an analyte species may not be effectively ionized without special conditions. Despite this limitation, APCI is generally applicable to a wide range of compounds under the appropriate conditions.

Charge transfer ionization proceeds via the pathway shown in Equation (13):

\[
M + R^+ \rightarrow [M - H]^+ + RH
\] (14)

Ionization by addition generally involves the formation of adduct ions. For example, \([M + CH_3]^+\) ions were observed for hydroxy-1,4-naphthoquinone in the presence of methanol and \([M + Na]^+\) ions and \([M + NH_4]^+\) ions have been observed.

Ipso-substitution reactions, as illustrated in Equation (15), have been described for aromatic compounds:

\[
C_6H_5Cl + NH_3^+ \rightarrow C_6H_5NH_3^+ + Cl^-\] (15)

A thorough review of positive ion reagents for low-pressure chemical ionization has been published. Although this review is not completely applicable to APCI because solvent molecules may predominate over added reagents, it still provides a useful background on gas-phase reactions for numerous reagents.

In addition to the cation formation reactions listed above, negative ion formation can also occur, but product anions must be detected separately from positive ions. Electron attachment is probably the simplest mechanism of negative ion formation, and can be considered a charge transfer mechanism as shown in Equation (16):

\[
M + e^- \rightarrow M^-\] (16)

The resulting open-shell (odd-electron) ions generally have a higher tendency toward fragmentation than closed-shell (even-electron) ions. Molecules with high electron affinities are likely to form ions by this mechanism. Several hydroxy-substituted PAHs exhibit M\(^-\) ions, but electronegative species such as halogenated organics are the most likely candidates for electron capture.

Although chlorinated organic compounds are expected to form M\(^-\) ions through electron capture, trichloroethylene (TCE) does not exhibit such ions by APCI. Instead, the halide attachment ions are seen. These ions take the form Cl\(^-(\text{TCE})_n\), and are formed through gas-phase attachment of Cl\(^-\).

Proton transfer, which is a common route for positive ion formation, can also result in the formation of negative ions via proton abstraction. These reactions (Equations 17 and 18) are similar to those forming positive ions, except that the neutral analyte molecule loses a proton to the reagent molecule or ion:

\[
M + R \rightarrow [M - H]^+ + RH\] (17)
\[
M + R^- \rightarrow [M - H]^+ + RH\] (18)

The \([M - H]^+\) ion is commonly found in negative ion spectra. A few examples include chloro- and nitrophenols, hydroxy PAHs, and several classes of pesticides.
Reaction with superoxide (Equations 19 and 20) is another possible route to the formation of negative ions:

\[
\begin{align*}
M + O_2^{-•} & \longrightarrow M^{-•} + O_2 & (19) \\
M + O_2^{-•} & \longrightarrow [M - H]^{-} + HO_2^{-} & (20)
\end{align*}
\]

These are simply charge exchange and proton transfer reactions involving superoxide. Oxygen or superoxide can also react with chlorinated aromatic analytes to yield [M – Cl + O]^- ions.\(^{(5)}\)

A review on fragmentation of even-electron organic anions is available.\(^{(23)}\) This review focuses on low-pressure ionization methods, but it still provides information that may be useful in determining the fragmentation of [M – H]^- and other even-electron negative ions formed by APCI.

1.1.3 Ion Extraction

Once ions are formed in the region of the corona discharge, these ions may interact with other molecules before being extracted into the low-pressure regions of the mass spectrometer. As mentioned above, the high pressure in the ion source region generally results in thermalization of ions, i.e. excess internal energy resulting from the ionization process is often dissipated through very-low-energy collisions, resulting in stabilization of the ions. In addition to this stabilization effect, multiple collisions favor thermodynamically stable products. Therefore, ions that are not stable undergo further reaction. In general, the distribution of ions sampled by the mass spectrometer consist of the most thermodynamically favored products appearing in the highest amounts, followed by smaller and smaller quantities of decreasingly favored products.

Beyond these thermodynamic considerations, extraction of the ions into the low-pressure region can also affect the distribution of ions. The aim of the extraction process is to transfer as many analyte ions as possible into the mass analyzer whilst maintaining the vacuum of the mass spectrometer. For the most part this involves selectively pumping away neutrals and transporting ions. Two-stage differential pumping systems are typically used to achieve this goal. Referring to Figure 2, once the ions are formed in the region of the corona discharge, the ions and neutrals are transported through the sampling cone. Only a small aperture is present in this cone, and therefore a majority of the gases are diverted to waste. The aperture is generally of submillimeter diameter. The back side of the sampling cone is maintained under a vacuum of around 1 mbar (via a rotary pump as illustrated in Figure 2). The pressure drop across the cone results in a supersonic expansion of gases from the high-pressure region into the low-pressure region.

The expansion consists of a silent zone bounded by the barrel shock and the Mach disk,\(^{(7)}\) as illustrated in Figure 4. Within the expansion zone, the molecules travel in relatively straight lines and, owing to the adiabatic expansion, ions are effectively cooled. The cooling results in stabilization of ions, most notably those with high internal energies, resulting in decreased fragmentation. In addition, the cooling can inhibit the break-up of solvent and analyte clusters, resulting in higher cluster ion signals.\(^{(5)}\)

After the sampling cone, the pressure is further reduced by a skimmer: another cone with a small aperture. If the skimmer is placed within the free jet expansion, sampling of the ions is efficient due to the directionality of the ions within the expansion.\(^{(7)}\) Beyond the barrel shock and the Mach disk, more random motion is observed, resulting in less-efficient collection. However, cluster ions formed in the free jet expansion (e.g. with water molecules) are often dissociated by collisions occurring in the Mach
disks. In Figure 2, the region behind the skimmer is maintained at around \(1 \times 10^{-3}\) mbar by a turbo pump. An additional orifice then allows ions to pass into a region of lower pressure (\(10^{-6}\) mbar) maintained by a diffusion or turbomolecular pump. Finally, the ions are passed into the analyzer region (\(10^{-7}\) mbar) via the source slit. Also shown in Figure 2 are a number of focusing devices, including electrostatic lenses, a hexapole, and even the sampling cone and skimmer. These optics maintain the path of the ions into the mass analyzer and prevent them from being pumped away with the neutrals.

The formation of cluster ions, especially from solvent and water, is a common problem in APCI. Use of a counter-current bath gas can reduce the abundance of cluster ion signals. Another method of minimizing cluster ion signals is to use the region between the sampling cone and the skimmer as a preanalyzer collision cell. By applying a small voltage between the sampling cone and skimmer lens (for the configuration represented in Figure 2), analyte ions are accelerated. Because the pressure is still relatively high, energetic collisions with background gas result. At low accelerating voltages, cluster ions are dissociated to give single ions without causing fragmentation of the ion. At higher voltages (100–200 V for the Figure 2 design), sufficient energy is imparted to the ions to cause collision-induced dissociation (CID). Such fragmentation events can be useful for structural determination and for more fundamental studies on fragmentation processes. Examples of in-source CID are illustrated in Figures 5 and 6 for N-(palmitoyl)sphingosine and 2,4-dinitrophenol.

### 1.2 Practical Use

In this section, important information for the use of APCI with commercial systems will be presented. The choice of solvent systems, the selection of solvent delivery systems, common positive and negative ion reagent systems, dynamic range and detection limit, APCI operation, and calibration will be discussed.

#### 1.2.1 Solvents and Solvent Delivery Systems

APCI systems typically operate in the range 0.2–2 mL min\(^{-1}\), although the optimum conditions may occur in a narrower range of flow rates. A high-quality HPLC pump is recommended for APCI work. The pump, however, must be capable of pulse-free operation. Otherwise, signal variations in the total ion current will be observed due to fluctuations in the intensity of background and analyte signals as the flow to the nebulizer is varied. Generally, these fluctuations are observed as regular variations in the signal, usually corresponding to the frequency of the pump piston(s). Pumps with flow compensation are preferred (maintaining constant flow under varying pressures and viscosities). Commercial pulse dampeners are available and can be added to a pump exhibiting unacceptable pulsation. As an alternative to reciprocating HPLC pumps, syringe pumps offer pulse-free operation. Syringe pumps are more commonly used for low-flow-rate applications. Typical HPLC injection valves can be used for introducing samples into the flow stream. As with any other HPLC application, the introduced sample should be miscible with the solvent system. For flow injection work, the use of special pulseless injection valves is necessary. With an ordinary valve, a pressure pulse results when the sample is introduced into the flow stream. This pulse results in a large signal spike in the mass spectrometer. In flow injection work, the spike appears at the same time as the analyte, causing significant interference. For HPLC applications, a pulse-free valve is not necessary because the analytes generally elute well after the initial pressure pulse.

The choice of solvents and flow rates is also generally set by the separation being performed. However, adjustment of the separation conditions may be necessary to optimize the APCI process. Both normal-phase (nonpolar mobile phase, polar stationary phase) and reversed-phase (polar mobile phase, nonpolar stationary phase) chromatography are compatible with APCI. Although early applications of high-performance liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry (HPLC/APCI/MS) used normal-phase chromatography, more recent applications, especially those investigating analytes in aqueous-based systems, generally rely on reversed-phase separations. Typical solvent systems use water–methanol or water–acetonitrile mixtures. The use of volatile buffers or ion pair agents is also common, and gradient systems are widely used. A few examples of isocratic and gradient mobile phases are listed in Table 3.

Although gradient elution is often used with HPLC/APCI/MS analysis, the use of limited gradient ranges is recommended to reduce possible desolvation problems. If a solvent composition change of greater than 25% is required, the following strategies can be employed to avoid problems. Postcolumn addition of organic solvent can be utilized to allow easier desolvation in the APCI interface. This approach generally limits the maximum HPLC flow rate to about 0.8 mL min\(^{-1}\), but allows the postcolumn addition of a calibration compound (as indicated in Figure 7). If a large gradient is necessary and it is impractical to add flow postcolumn, the temperature of the nebulizer/desolvation chamber should be ramped to give higher temperatures at high aqueous content and lower temperatures at high organic content.

The background ions observed in APCI will vary as a function of the mobile phase composition. Background
ions for a water–methanol–formic acid mobile phase in positive and negative ionization modes are shown in Figure 8. In addition to changes in background ions, the degree of solvent adduct formation also varies with solvent composition. Lower degrees of solvent adduct formation have been observed with water–acetonitrile mixtures than with water–methanol mixtures.

Overall, HPLC/APCI/MS is well suited for the analysis of a wide array of compounds, ranging from nonpolar to polar, and encompassing thermally labile and thermally stable compounds. However, sometimes a compromise must be made between optimum separation conditions and optimum APCI conditions. An example is the practical limitations to gradient elution as described above. In addition, only relatively volatile buffers are acceptable. Finally, ionization of an analyte depends on its gas-phase reactivity (via reaction pathways described in section 1.1.2). In general, compounds with high GPBs will be ionized efficiently in the positive ion mode. Compounds exhibiting significant GPAs will produce abundant negative ions. Careful selection of mobile phases and/or the use of low levels of modifiers can...

### 1.2.2 Atmospheric Pressure Chemical Ionization Operation

The first task in any MS experiment is to obtain an ion beam. In order to do so, both ion formation and ion transport into and through the mass spectrometer must be achieved. Typically, APCI interfaces are combined with magnetic sector or quadrupole mass spectrometers. Although the details of adjusting the mass spectrometer parameters will vary by instrument type, the adjustment of the APCI source itself is similar for both types of spectrometers.

For tuning of the mass spectrometer, it is often possible to observe water cluster ions. In fact, such clusters can often be seen without any solvent flow due to trace amounts of water vapor in the gas stream or residual water vapor in the interface. With the corona needle at...
high voltage, water cluster ions of the form \([\text{H}_2\text{O}]_n\text{H}^+\)
may be found at various \(m/z\) ratios, including 55, 73, and 91. Larger clusters with \(m/z\) as high as \(~1200\) may also be observed. Although solvent cluster ions may be used for mass calibration, their intensities may be variable, which may make it difficult to use them for routine mass calibration. The formation of water clusters is often dependent on the nebulizer temperature, with more clusters formed at low temperature. However, thermally labile analytes may not survive high nebulizer temperatures.

Tuning and mass calibration can often be performed using the same species. In addition to solvent cluster ions, several added reagents may also be used for these purposes. Optimization of the APCI interface requires a constant flow of a suitable compound to the interface over a period of several minutes. Flow injection methods are not suitable for this purpose, and direct introduction of a tuning solution is usually necessary. For positive ions, a useful tuning solution is 3-picoline (0.005% v/v) in 1:1 water–acetonitrile. This solution produces \([M + \text{H}]^+\) and \([M + \text{acetonitrile}]^+\) adduct ions of 3-picoline at \(m/z\) 94 and 135. The high volatility of 3-picoline allows for continuous infusion of this solution without causing source contamination. Alternatively, pyridine may be used at the same concentration, yielding an \([M + \text{H}]^+\) ion at \(m/z\) 80. Pyridine, however, is somewhat more hazardous than 3-picoline. Caffeine at 1 ng \(\mu\text{L}^{-1}\) in 1:1 water–acetonitrile yields \([M + \text{H}]^+\) and \([M + \text{acetonitrile}]^+\) ions at \(m/z\) 195 and 236. Source contamination is generally not a problem with this solution, although slightly longer washout times may be necessary in order to perform trace analyses near these masses. Finally, polyethylene glycol (PEG; 0.001% v/v PEG-200) in 1:1 water–acetonitrile may also be used for tuning on positive ions. PEG generally requires long washout times for complete removal from the interface.

For negative ion tuning, solutions of organic acids are typically suitable. For example, 1% acetic acid in 1:1 water–acetoniitrile or 1:1 water–methanol yields a strong signal with little risk of source contamination. Anthraquinone at 1 ng µL⁻¹ provides a strong signal at m/z 207, and p-nitrophenol yields a strong signal at m/z 138.

Table 4 lists some additional calibration compounds for APCI work. For low mass resolution, mass calibration can be performed prior to analyte analysis, with complete removal of the calibrant prior to analyte introduction. In contrast, high-resolution work requires continuous introduction of the calibrant simultaneously with the analyte. For chromatographic work, the calibrant is usually added postcolumn, as illustrated in Figure 7.

1.2.3 Detection Limit and Dynamic Range Considerations

Detection limits for APCI are highly dependent on the analyte and the conditions. Of course, optimization of the source parameters for the analyte is necessary to achieve optimum results. As with any other mass spectrometric technique, the best detection limits are achieved when performing selected ion monitoring (SIM). In this technique, only the mass of the most abundant ion is observed. The result is integration of the analytical signal for the full measurement period, whereas scanning the full mass range results in integration of a single ion for only a fraction of the total acquisition time. The disadvantage of SIM is that only information about one ion (or sometimes several) is recorded. As a result, fragmentation patterns cannot be recorded and compounds of other, perhaps unanticipated, m/z will not be observed. SIM measurements often are carried out for several ions instead of a single ion. In this manner, expected fragment ions can be observed to verify compound identity, and multiple analytes can be measured. In addition, SIM measurements can be programmed to correspond to elution times of the analytes. For example, in a chromatographic analysis of A and B, when compound A elutes, a series of ions corresponding to A are monitored. Similarly, when compound B elutes at a later time, a different series of ions corresponding to B are monitored.

Absolute detection limits for APCI have been reported to be as low as 2 pg (~7 fmol). Concentration detection limits of 10 ppt (parts per trillion) have been reported. More typical detection limits are in the low parts per billion range, or for absolute detection limits in the 100-pg to low-nanogram range. Detection limits for APCI are primarily dependent on the ionization efficiency of the analyte (which can be close to 100%) and the transmission efficiency of the ions to the detector. In addition to optimization of the source parameters, selecting the best reagent gas (usually governed by the mobile phase) and the best mode of operation (positive or negative ion mode) is likely to improve detection limits.

Linear ranges reported for APCI calibration curves are generally quite narrow. Reported linear calibration ranges are of the order of 1–4 orders of magnitude. Nonlinearity at higher analyte concentrations may be caused by depletion of the reagent ions by the presence of large amounts of analyte molecules. In addition, the presence of other compounds in the sample matrix (e.g. additional constituents, additives, contaminants) can alter the ionization efficiency by competing for reagent ions. Co-elution of compounds in chromatographic separations can therefore pose serious problems, either by degradation of detection limits or by causing nonlinear calibrations or matrix effects. The presence of certain mobile phase constituents, such as buffers, can also degrade detection limits if the additive is a significant consumer of reagent ions.

1.3 Applications

The number of research publications on APCI has increased steadily since the early 1990s. In 1997, over 100 journal articles were published on the topic, accounting for about 20–30% of all chemical ionization articles. The increase in publications employing APCI also corresponds to broader application of the technique to many different sample types. A comprehensive review of all APCI publications will not be presented here; however, a survey of the recent literature will be presented to illustrate the breadth of applications and to provide specific examples of conditions used in actual APCI analyses. APCI has been applied to the analysis of food products, pharmaceuticals, environmental samples, biological and medical samples, plant materials, fullerenes, catalysts, industrial products, as well as other sample types.
Food and pharmaceutical analyses include the determination of flavors and nutrients, and the determination of compounds having pharmaceutical value. Melatonin was analyzed by liquid chromatography/atmospheric pressure chemical ionization/tandem mass spectrometry (LC/APCI/MS/MS) in various commercially available formulations. An ion trap mass spectrometer was used, and linear response ranges were 0.5–5 ng on-column. The mobile phase was 20:80 acetonitrile–water (1% acetic acid, 10 mM ammonium acetate). Compound identity was verified by monitoring the [M + H]⁺ ion and a single daughter ion after CID of the quasimolecular ion. Volatile nitrosamines in dry sausage were determined by LC/APCI/MS/MS, and evidence was found for the formation of nitrosamines during ripening of dry sausages by reaction of residual nitrite with biogenic amines. LC/APCI/MS/MS analysis of triacylglycerols formed following reaction of residual nitrite with biogenic amines increased with increasing degree of unsaturation of the fatty acid moiety and the number of double bonds. Isolavones, especially from soy, can reportedly lower the risk of several chronic diseases. In order to investigate such benefits, a method for isoflavonoid analysis was developed utilizing LC/APCI/MS/MS. Specificity in isoflavonoid identification was achieved by CID using a triple quadrupole mass spectrometer. The technique was demonstrated to have broad applications for phytoestrogen analysis.

Analysis of food-derived fats has also been performed with APCI techniques, including triacylglycerols from milk fat and from vegetable and berry oils. These analyses utilized either supercritical fluid chromatography (SFC) or HPLC with interfacing to an APCI mass spectrometer. For SFC, methanol vapor was added to the ionization chamber as a reagent species. Under these conditions, [M + H]⁺ and [M – RCOO]⁻ ions of triacylglycerols were observed. These ions were used to define the molecular weight and fatty acid constituents, respectively. Supercritical fluid chromatography/atmospheric pressure chemical ionization/tandem mass spectrometry (SFC/APCI/MS/MS) analysis of triacylglycerols was achieved using an unmodified commercial interface. A triple quadrupole mass spectrometer was used, and ionization was achieved by introduction of vapors of methanol, isopropanol, water, or ammonium hydroxide in methanol. The triacylglycerols formed [M + H]⁺ and [M – RCOO]⁻ ions, except with added ammonium hydroxide, where [M + NH₄]⁺ ions were observed instead. The abundance of the [M + H]⁺ ions increased with increasing degree of unsaturation of the triacylglycerol, and the abundance of the [M – RCOO]⁻ ion depended on the regiospecific distribution of the fatty acid moiety and the number of double bonds. Mottram et al. utilized nonaqueous reversed-phase HPLC/APCI/MS with propionitrile as the mobile phase. This method also yielded [M + H]⁺ and [M – RCOO]⁻ ions, allowing for regiospecific analysis of the triacylglycerols. SFC/APCI/MS has been utilized for analysis of Cannabis by forensic laboratories. This study used CO₂ with 2–7% methanol as mobile phase. No additional reagent was added for ionization. Protonated molecules were observed for each of the four important analytes. Increased cone voltages were used to perform in-source CID to allow for the additional structural information needed to verify compound identity. Carotenoids are important biological pigments that exhibit provitamin A activity, function as antioxidants, are possible inhibitors of carcinogenesis, may enhance immune response, and may prevent cardiovascular disease. HPLC/APCI/MS has been applied successfully to the analysis of this class of compounds. Carotenoids exhibited M⁺ or [M + H]⁺ and [MH – 18]⁺ ions in positive mode and M⁻ or [M – H]⁻ ions in negative mode. The type of ion observed was solvent dependent, with polar solvents increasing the abundance of protonated carotenoids and nonpolar solvents favoring the formation of radical molecular ions.

Environmental applications of APCI often involve analysis of polar compounds that cannot be analyzed by gas chromatography. Several pesticides and degradation products have been analyzed by HPLC/APCI/MS in both positive and negative ion modes. Separations used mobile phase gradients of methanol–0.1 M ammonium acetate (pH 4.5) or acetonitrile–water. Of the 27 compounds studied, 24 yielded positive ions and 13 yielded negative ions. Most compounds gave [M + H]⁺ or [M – H]⁻ ions, although a few compounds exhibited [M + Na]⁺ or [M – CH₃]⁻ ions. With a cone voltage of 20 V, slight to moderate fragmentation was observed. Increasing the cone voltage to 40 V resulted in significant fragmentation, often resulting in complete loss of molecular weight information. The linear dynamic range was two orders of magnitude or less. Substituted phenols have also been determined in water by APCI techniques. Phenols were separated using a mobile phase of acetonitrile–0.05% acetic acid (aq) (50:50). Postcolumn addition of 100 mM dimethylamine in acetonitrile–water (50:50) was used to improve ionization efficiency in negative ion mode. With the extraction voltage set at −20 V, [M – H]⁻ was the base peak for all compounds studied. Increasing the extraction voltage to −50 V resulted in significant fragmentation, although the pseudomolecular ion was still observed. For these compounds, detection limits for APCI were better than those observed by ESI. Other reports have also indicated [M – H]⁻ ions for chloro-, nitro-, and other substituted phenols. PAHs and metabolites have also been studied by APCI. Polar metabolites of benzo[a]pyrene were determined in the negative ion mode. Both M⁺ and [M – H]⁻ ions were observed, and the linear dynamic range
was 0.1–10 ng. The metabolism of nitrofluoranthenes by fungi was studied using LC/APCI/MS. Acetonitrile–aqueous ammonium acetate (50:50) was used as the mobile phase. Low cone voltages were used to produce in-source CID for improved structural analysis. Additional reports on azo dyes, pesticides, were used to produce in-source CID for improved structural analysis. Additional reports on azo dyes, pesticides, and naturally occurring pesticides are available.

Biological and medical studies make up a large percentage of published APCI papers. Negative APCI was used to analyze bacteriohopanepolyols, which are abundant membrane constituents in certain bacteria. Dichloromethane was added postcolumn and was used to promote the formation of chloride adduct ions. Primarily single chloride addition ions ([M + Cl]−) were observed. Dextruxins (cyclic hexadepsipeptides) produced by fungi are insecticidal, phytotoxic, antiviral, nematocidal, and immunomodulating compounds. LC/APCI/MS with in-source CID was used to screen for dextruxins.

Acetonitrile–water (56:44) was used as the mobile phase and mass spectra were collected in the positive ion mode by employing a double-focusing mass spectrometer. Retinol and retinyl palmitate were analyzed in human serum by HPLC/APCI/MS. APCI, in contrast to ESI, yielded a linear response over four orders of magnitude. Both compounds gave the same base peak, resulting from loss of water or loss of palmitic acid, respectively. Sampatrilat, a developmental hypertension and congestive heart failure medication, was analyzed by high-performance liquid chromatography/atmospheric pressure chemical ionization/tandem mass spectrometry (HPLC/APCI/MS/MS). Despite the general applicability of APCI to analyses of polar compounds, this dicarboxylic acid could not be ionized without prior derivatization of the carboxylic acid groups with BF3–methanol. The resulting carboxylic acid ester was ionized in positive ion mode to yield [M + H]+. Sphingolipids, glycerophospholipids, and plasmalogens were analyzed from bovine brain, human serum, and porcine ingolipids, glycerophospholipids, and plasmalogens were analyzed by APCI using both positive and negative ion modes.

The underivatized compound exhibited [M − H]− ions with little fragmentation, but no ionization could be achieved in positive ion mode. The methyl ester derivative yielded predominantly [M + NH4]+ ions with some [M + H]+ also observed. Separations utilized acetonitrile–water or methanol–water mixtures with 65 mM ammonium acetate. Numerous other studies on biological and biomedical applications of APCI are available.

For a summary of the APCI applications mentioned here, see Table 5.

2 ELECTROSPRAY IONIZATION MASS SPECTROMETRY

ESI is a technique that ultimately transfers ions from a solution that is emerging from a metal capillary held at high voltage, into the gas phase. Often the ions observed in the mass spectrum were predisposed to exist in ionic form in solution, either as salts or via association of neutral molecules with small cations or anions present in solution. Owing to the fact that most chemical and biochemical processes deal with compounds existing in solution, ESI has led to a wide variety of applications in chemistry, biochemistry, pharmaceuticals, and environmental science. Other mass spectrometric ionization techniques are less successful for generating intact gaseous ions from large, highly polar, nonvolatile species.

Electrospray was first introduced by Dole et al. in 1968 as a method to charge synthetic polymer molecules. In 1984, Yamashita and Fenn successfully coupled an electrospray ion source to a single quadrupole mass spectrometer. Independently and at the same time in the Soviet Union, Aleksandrov et al. were developing an ESI time-of-flight mass spectrometer. The early ESI/MS achievements of Fenn, especially the demonstration that large biological molecules could be analyzed on a mass analyzer of limited m/z range because of the ability to multiply charge analyte molecules, led to the rapid popularization of this technique. This ability to obtain extensive multiple charging of analyte molecules distinguishes ESI from other mass spectrometric ionization techniques. Since its advent, much attention has been directed toward examining the fundamental mechanisms of ion formation in ESI, as well as the design and improvement of instrumentation, the optimization of experimental parameters for specific analytical applications, and its interfacing to HPLC and capillary electrophoresis.
A variety of molecules, ranging in polarity from ionic, to polar, to even nonpolar compounds, can be detected via ESI/MS. Included in this list\(^\text{69}\) are: species that are inherently charged in solution, such as organic or inorganic salts; polar neutral species exhibiting association/dissociation of small ions in solutions (e.g. \(\text{H}^+\), \(\text{Na}^+\), \(\text{NH}_4^+\), etc.) such as multiply protonated/deprotonated proteins; and nonpolar species that undergo electrochemical oxidation/reduction at the ESI capillary (inherent to the positive/negative ion ESI process), such as PAHs.\(^\text{70–72}\) A restriction is that all analytes must dissolve in a solvent exhibiting moderate conductivity;\(^\text{73,74}\) methanol and water mixtures are most commonly used for ESI/MS.

Compared to other desorption/ionization methods, such as liquid secondary ion MS,\(^\text{75}\) electro spray is a “softer” ionization method, hence a lower degree of fragmentation is inherent to the ionization process. In ESI/MS, the internal energies of desorbed, charged analyte molecules are dissipated during the desolvation stage when loosely bound solvent molecules dissociate from the final charged cluster. Because of the gentle nature of the transfer from solution into the gas phase, the three-dimensional structures of ions in solution are relatively unperturbed upon transfer into the gas phase; it appears to be the least perturbed of all mass spectrometric ionization techniques. This feature allows the examination of aspects of three-dimensional structure that are inaccessible by other MS approaches, including the propensity for hydrogen/deuterium exchange\(^\text{76}\) (indicative of molecular conformation and intramolecular binding), as well as characteristics of weakly bound noncovalent interactions (e.g. enzyme–substrate, protein–protein, protein–cofactor, protein–metal ion interactions,\(^\text{77,78}\)).

Despite the rapidly growing number and types of applications of ESI/MS in various areas, questions still exist regarding the precise mechanism of ion formation. A more complete understanding of the underlying mechanism may indicate new directions for future uses of ESI/MS.

\(b\) Observed only for methyl ester derivative.
2.1 Fundamental Mechanism of Electrospray Ionization
The production of gas-phase ions from solution via electrospray can be separated into four key steps:

- electrochemical processes occurring at the ESI capillary;
- charged droplet formation at the tip of the ESI capillary;
- droplet evaporation and Coulomb fission;
- formation of gas-phase ions from small, highly charged droplets.

The following sections deal with these steps in the order in which they occur.

2.1.1 Electrochemical Processes Occurring at the Electrospray Ionization Capillary

Electrospray is an ionization technique that employs a high voltage to produce an excess of charged species of one polarity in solution. These charged species serve to initiate liquid break-up and they provide a means to impart charge onto solution-phase analytes that ultimately appear as gas-phase ions in the mass spectrum. A high voltage (typically about 3 kV in positive ion mode, or about −3 kV in negative ion mode) is applied to the metal capillary through which the sample solution is driven via pressure. The exit of the capillary is usually located about 1–3 cm from the sampling aperture (counter-electrode) in the ESI source. The value of the electric field, $E_c$, in the air at the capillary tip can be estimated from Equation (21)\(^{(86,95)}\) if the counter-electrode is large and planar compared to the working electrode:

$$E_c = \frac{2V_c}{\left(r_c \ln(4d/r_c)\right)} \quad (21)$$

where $r_c$ is the capillary outer radius, $V_c$ is the applied electric potential, and $d$ is the distance from the capillary tip to the counter-electrode. The electric field, which is proportional to $V_c$, typically has a value of $\sim 10^6 - 10^7$ V m$^{-1}$. In response to the imposed electric field, ionic species emerging from the ESI capillary undergo electrophoretic movement. In the positive ion mode, anions migrate in the direction of the ESI capillary held at high positive potential, whereas cations migrate in the opposite direction, toward the meniscus of the emerging liquid. The force of the electric field acting upon positive ions is counteracted by the surface tension of the liquid, resulting in the formation of a dynamic cone of liquid referred to as a “Taylor cone”.\(^{(86)}\) Because of the high voltage difference between the ESI capillary and the counter-electrode (ESI capillary positive for positive ion ESI/MS), oxidation reactions occur at the metal–solution interface of the ESI capillary, such as H$^+$ production from water, as shown in Equation (22)\(^{(81–83)}\):

$$2H_2O = O_2 + 4H^+ + 4e^- E^0 (\text{vs SHE}) = 1.229 \text{V} \quad (22)$$

Conversely, in the negative ion mode, electrophoretic movement of anions and cations is reversed relative to the above discussion, and reduction reactions occur at the metal ESI capillary. In order to sustain a continuous production of charged droplets of one polarity, it is imperative to have an electrochemical mechanism whereby ions are continually produced at the ESI capillary. Similarly, to maintain a fixed voltage at the counter-electrode, where there is a continuous arrival of charged species of one polarity, it is necessary to perform a second electrochemical reaction. In the positive ion mode, requiring oxidation at the ESI capillary, the second reaction must be a reduction at the counter-electrode. Logically, the counter-electrode reaction in the negative ion mode is an oxidation. When this second reaction occurs, it may be thought of as completing the electrical circuit of the ESI source, which has been described thereby as a special type of electrolytic cell (Figure 9) in which electrolysis maintains the charge balance to allow continuous production of charged droplets.\(^{(81,82,84,85)}\)

The electrospray source has been further likened to a controlled-current electrolytic cell.\(^{(82)}\) This implies that in positive ion experiments, in order to supply a certain

![Figure 9](image-url)
ESI current, the oxidation process that occurs at the ESI capillary is that characterized by the lowest oxidation potential, as determined by the solution components, and the materials present in the capillary. If the arrival rate of these most electroactive species to the metal—solution interface is insufficient to produce the required current, the next most easily oxidized species will undergo electron removal, and so on, until an adequate current is achieved.

The observation of Zn$^{2+}$ ions in the positive ion ESI mass spectrum of a solution sprayed through a zinc metal ESI capillary$^{(84)}$ was given as evidence of the inherent electrochemical nature of ESI. More recently, Van Berkel et al.$^{(83)}$ reported pH changes of as much as 4 pH units during the ESI process. The pH lowering in the positive ion mode was attributed to the oxidation of water to produce H$^+$ in the employed aqueous solution when an inert platinum ESI capillary was used in place of a stainless steel capillary. This latter evidence provides proof that solution-phase oxidation/reduction reactions are inherent to the ESI process. Corrosion (oxidation) of certain components of stainless steel capillaries was proposed to serve as a type of redox “buffer”, thus attenuating the pH change. Moreover, pH changes could be avoided at the platinum ESI capillary when an easily oxidized species (e.g. KI as redox buffer$^{(85)}$) was added to suppress the oxidation of water. pH changes attributable to the electrochemical reaction of water may have a profound effect upon the appearance of the mass spectrum, especially when low flow rates$^{(83)}$ are employed (such as in the nanospray mode) and electrochemical reaction products are undergoing only minimal dilution.

2.1.2 Charged Droplet Formation at the Tip of the Electrospray Ionization Capillary

The above-described electrochemical redox processes lead to the continuous production of charged droplets of a given polarity (Figure 9), as determined by the polarity of the applied potential. In the positive ion mode, as the excess positive charges accumulate near the end of the capillary, they come under the influence of the imposed electric field. The positive ions emerging from the capillary are thus attracted to the relatively negative “pole” that is the counter-electrode. This attraction causes the liquid to elongate in the direction of the counter-electrode. However, the surface tension of the liquid serves to provide an opposing force to hold the solution together. The result of these two opposing forces is the formation of a dynamic cone of liquid at the tip of the stainless-steel capillary, i.e. the “Taylor cone”. At the apex of the Taylor cone a “jet” of liquid emerges, wherein the charge density is sufficiently high to overcome the surface tension, and droplet break-up results. This process produces a fine spray of charged droplets that head toward the counter-electrode owing to a combination of the potential gradient and a weak pressure gradient. The droplets carry excess positive charges and stability is gained upon droplet break-up because the repulsive force between like charges is spread over a larger surface area. Of course, in the negative ion mode, ESI droplets contain excess negative charges.

According to Pfeifer and Hendricks,$^{(86)}$ the radius of the generated charged droplets will increase with increasing flow rate or decreasing conductivity. Therefore, the use of low flow rates and high-conductivity solutions will result in the production of very small droplets. The stream of charged droplets emerging from the ESI capillary can be thought of as the “ESI current”, and its magnitude is identical to the current generated by electrochemical reactions at the ESI capillary. The steadiness of the ESI current (e.g. as measured at the counter-electrode) is an indicator of the stability of the generated spray. The measured current also provides a quantitative estimate of the total number of ions that could be converted into gas-phase ions.

2.1.3 Droplet Evaporation and Coulomb Fission

After the charged droplets are produced at the tip of the electrospray capillary, heating induces evaporation of high-volatility solvent molecules. As the solvent evaporates, the size of the droplets becomes smaller but the charge on the droplets remains constant. Therefore, the electrostatic repulsion increases until it reaches the so-called “Rayleigh stability limit” where the force of electrostatic repulsion between like charges becomes greater than the surface tension force holding the droplet together. The droplet becomes unstable when the Rayleigh limit is reached, as defined by the Rayleigh equation (Equation 23):$^{(87)}$

\[
q_R = 8\pi\varepsilon_0 R^3 n^{1/2}
\]

where $q_R$ is the excess charge on the droplet of radius $R$, $\gamma$ is the surface tension, and $\varepsilon_0$ is the permittivity of the vacuum.

As the Rayleigh stability limit is approached, the droplets undergo what is referred to as “Coulomb fission”, which is essentially a break-up of the droplet into smaller “offspring droplets”. Figure 10 is a schematic depiction of the Coulomb fission process that generates offspring droplets.$^{(81)}$ The driving force behind this process is that the repulsive force of the like charges is alleviated if the charges can be spread over a larger surface area; this is made possible only if the droplet is sheared. Droplet fission into two particles of nearly equal mass and charge (i.e. “even fission”) is not observed. Instead, the charged droplets are not static entities, but
The conductivity of the solution. The size of droplets that leave the capillary depends upon the flow rate and the conductivity of the solution.

The size of droplets that leave the capillary depends upon the flow rate and the conductivity of the solution. Upon further shrinkage of the offspring droplets, the mass ratios than the parent droplets that produced them. The offspring droplets will thus have higher charge-to-mass ratios than the parent droplets that produced them. Upon further shrinkage of the offspring droplets, the uneven fission process may repeat itself a second and, perhaps, a third time before gas-phase ions are generated.

The above description indicates that the initial charge and droplet size are very important in determining when gas-phase ions after the radii of the droplets decrease to a given size. This process is called the ion evaporation mechanism. In this mechanism, Iribarne and Thomson argued that the charged droplets are so small (radius < 10 nm) that solvent evaporation could make the electric field on the surface sufficiently high to emit solvated ions from the solution phase into the gas phase before the Rayleigh limit was reached. They proposed that at a certain intermediate stage, the high charge density on the charged droplet surface was sufficient to lift a charged . The fundamental difference between the charged residue mechanism and the ion evaporation mechanism is in how an analyte molecule becomes separated from other solute molecules in the droplet, although in either mechanism, both solvent evaporation and Coulomb repulsion are the driving forces leading to the formation of gas-phase ions. In the ion evaporation mechanism, separation is realized by the ion desorption/emission of a single solvated analyte ion carrying some of the droplet’s charge, thus alleviating Coulomb repulsion to some degree upon departure. In the charged residue mechanism, the separation comes from the repetitive fission events that produce the ultimate small charged droplets that contain only one analyte molecule (the gas-phase ion precursor). However, it is difficult to distinguish the phenomenon of desorption of a single solvated ion from a parent droplet, from that of a Coulomb fission event that produces an ultimate droplet that contains only one analyte molecule. Moreover, any
prediction of a difference in the number of charges or the degree of solvation found in a desorbed ion produced according to the ion evaporation mechanism, or those found in an ultimate droplet produced by the charged residue mechanism, are likely to be quite subtle. Nevertheless, a growing consensus has emerged that at least the ESI-generated ions of very large molecules are formed according to a charged residue scenario.\(^{(93–95)}\)

### 2.2 Instrumentation

Initial charged droplet formation in ESI occurs at atmospheric pressure but all mass analyzers for MS will operate correctly only under high vacuum. Therefore, an early challenge of electrospray source design was to couple efficiently an atmospheric pressure spray to the high-vacuum mass analyzer environment in order to maximize gas-phase ion production and transmission. Thus, the ESI mass spectrometer must: optimize the efficiency of liquid break-up; maximize the generation of gas-phase ions; and maximize the transport of ions through the mass spectrometer.

#### 2.2.1 Electrospray Ionization Source Construction and Operation

A schematic diagram of an ESI source\(^{(96)}\) is presented in Figure 11. The high-voltage arrangement required to initiate the ESI process is usually obtained in one of two ways: either the high voltage is applied to the metal ESI capillary with the counter-electrode being the low-potential end; or the metal capillary is held at or near ground while the counter-electrode is the high-voltage end. The source and sprayer are rarely both connected to high-voltage power supplies. A consideration that may influence the preferred arrangement is whether or not on-line separation techniques such as capillary electrophoresis are to be performed. Conventional capillary electrophoresis is usually conducted by applying 20–30 kV between cathode and anode, and separation is based upon differing electrophoretic mobilities in the capillary in response to the imposed electric field. In capillary electrophoresis/MS experiments, if the source vial (anode) is held at 20 kV, while the cathode is set at the high voltage required for electrospray, say 4 kV, the voltage drop across the capillary will be reduced to 16 kV and a longer separation time may result.

The required operation of ESI sources at high voltages creates very high charge densities at the sharp edges of the metal capillary tip; hence electron emission can occur, leading to initiation of a gas discharge (corona discharge) between the ESI capillary and the counter-electrode. This type of discharge is difficult to avoid completely, and it is especially prevalent in the negative ion mode and when the conductivity of analyte solutions is low. Electrical discharge should be minimized because it causes instability in charged droplet production (spray instability) and can change the appearance of mass spectra. To do so, the electric field is normally operated at the minimum value required to initiate formation of the Taylor cone and concomitant gas-phase ion production. Electron-scavenging gases, such as oxygen or SF\(_6\),\(^{(97)}\) have been added to the ESI source chamber and chlorinated solvents, such as chloroform,\(^{(98)}\) have been added to sample solutions to reduce the problem.

#### 2.2.2 Position of the Electrospray Capillary

Gas-phase ions are generated from charged droplets after solvent evaporation and Coulomb fission. The droplets, formed at the tip of the electrospray capillary, can be produced with a distribution of sizes and number of excess charges. The optimum positioning of the ESI capillary relative to the counter-electrode (Figure 12a) will depend upon several factors. First of all, for a given voltage difference between the ESI capillary and counter-electrode, the electric field will drop off as the distance between the two is increased. On the other hand, the capillary must not be too close to the counter-electrode because droplets may not be sufficiently desolvated upon entering the mass spectrometer. Of course, larger droplets are likely to be more susceptible to incomplete desolvation. Off-axis positioning of the ESI capillary can offer increased sensitivity, whereas diagonal positioning appears to be more effective for pneumatically assisted electrospray (Figure 12c) because it affords higher stability and no loss in sensitivity. Both seem to help prevent contamination of the sampling orifice. The position of the sprayer, therefore, plays an important part in determining the quality of obtained mass spectra, including sensitivity. For pneumatically (or...
2.2.3 Nebulization at High Flow Rate

High-flow-rate electrospray is especially designed for the purpose of on-line coupling of liquid separation techniques such as HPLC to ESI/MS. It has been established that low ESI flow rates result in high ion desorption rates, which implies high sensitivity in detection. The practical upper limit to flow rate for “pure” electrospray (i.e. no use of nebulizing gas) is ~10–20 µL min⁻¹, depending on the composition of the solvent. In these microliter per minute flow regimes, the ESI technique is characterized as “concentration sensitive” (i.e. signal strength is considered to be proportional to concentration), whereas at extremely low flow rates of tens of nanoliters per minute, where ionization efficiency can approach 100%, ESI can be described as “mass flux sensitive” (i.e. response is proportional to the absolute quantity or “mass” of material present).

To meet the demands for the use of the ESI mass spectrometer as a detector for LC separations, special consideration had to be given to ESI source design, with the aim of increasing the inlet flow tolerance to accommodate the high flow rates (e.g. up to 2 mL min⁻¹) used with conventional HPLC columns. The most common approach used to handle high solution flow rates (e.g. 20 µL min⁻¹–2 mL min⁻¹) is to add a counter-current of “bath gas” or pneumatically assisted nebulization, as shown in Figure 12(c), to facilitate liquid break-up. This type of device relies upon the shearing force of nitrogen being delivered at high pressure to the region where solution is emerging from the ESI capillary. Both gas and liquid are forced out of a small orifice, resulting in aerosol formation.

Ultrasonic nebulizers (Figure 12d) have also been employed to assist with liquid break-up at higher flow rates. In those devices, it is the ultrasonic vibrations that assist in shearing the liquid emerging from the ESI capillary. Pneumatically assisted nebulizers and ultrasonic nebulizers are particularly useful for sample solutions of high aqueous content, including mobile phases used in reversed-phase LC. However, both approaches must still rely on an imposed electric field for droplet charging.

At flow rates above about 200 µL min⁻¹, efficient droplet evaporation is absolutely imperative. If it is not achieved, ionization efficiency, and thus sensitivity, can be seriously impaired. Often the easiest approach to overcoming an excessively elevated elution rate from an HPLC column is to resort to “postcolumn splitting”, where a certain proportion of the effluent exiting the column is diverted away from the mass spectrometer. In theory, this approach will not result in sensitivity loss because at high flow rates ESI/MS is considered to be a “concentration sensitive” technique. Alternatively, additional thermal energy can be provided to enhance droplet evaporation. Three commercial approaches have been employed for this purpose: heating the nebulizing gas; introducing a desolvation region consisting of a long, heated metal capillary; and introducing resistive heating externally to various regions of the ion source. In order to desolvate effectively, one must combat the inherent cooling property of the gas undergoing expansion as it enters the mass spectrometer. This requires a significant amount of heat input to raise the temperature by several hundred degrees. Although most of the thermal energy is consumed during desolvation, some risk of thermal degradation may be introduced for certain compounds that are highly thermally labile.
2.2.4 Nanoflow Regime

Both the number of charges per droplet and the radius of the initial droplet are dependent on the solution flow rate. As rationalized by Wilm and Mann, the higher surface-to-volume ratio of smaller droplets allows a higher efficiency of desorption of charged analyte molecules. Moreover, a smaller-aperture capillary tip gives a narrower dispersion of sprayed droplets and hence less sample is lost due to inefficient transfer into the mass spectrometer. For these reasons, the overall ionization efficiency for a given analyte can increase by as much as two orders of magnitude when the flow rate is decreased from the conventional microliter per minute range to ~20 nL min\(^{-1}\). The latter flow rate in the so-called “nanoflow regime” (i.e. ~10–100 nL min\(^{-1}\)) yields droplet sizes of approximately 200 nm. The improved ionization efficiency has resulted in reports of extremely low limits of detection, such as 5 \text{amol} \mu\text{L}^{-1} for methionine–enkephalin and 32 \text{amol} \mu\text{L}^{-1} for neurotensin.

When analyzing a small volume of a very valuable sample, as is often the case when performing trace analyses of samples of biological origin, low flow rates also allow for reduced sample consumption and extended acquisition times. This combination can afford the maximum signal-to-noise ratio via signal averaging over a long time period. Long acquisition times can also facilitate tuning and preparation for more complicated experiments such as tandem MS studies. Extensive development of nanoflow regime sprayers occurred in the mid- to late-1990s. The challenge was to achieve stable electrospray signals at the very low flow rates. The approach used to accomplish this was to reduce the diameter of the sprayer aperture, because lower flow rates require smaller diameters for optimum stability. Theoretical treatment gives an approximate value of 20 nL min\(^{-1}\) for a finely drawn borosilicate capillary having a 1–3 \text{μm} i.d. aperture that is coated with silver or gold. The sputter-coated metal serves to provide electrical contact to the capillary tip. Liquid break-up at the capillary exit is attributable exclusively to the electrical stress due to the imposed high voltage (i.e. no nebulization assistance is employed). Therefore, the flow rate is determined (and regulated) via the field strength, the solvent viscosity and surface tension, the electrolyte concentration, and the capillary tip diameter. It is possible to work with 100% aqueous solvent at low flow rates (~20 nL min\(^{-1}\)). For such a low-diameter capillary aperture, blockage (clogging) is a potential problem, so solutions need to be filtered before use.

2.2.5 Transport into the Vacuum Region

As the ions are transferred from the atmospheric pressure region to progressively lower-pressure regions of the mass spectrometer, the “spray plume” expands and a strong cooling effect results. Remaining solvent–ion aggregates follow a straight line along the axis of the nozzle, whereas gas molecules far away from the axis have a random motion and will be pumped away. Immediately beyond the cone orifice, a barrel shock wave exists (Figure 13) where many collisions occur between ions and gas molecules. Inside this shock wave is the so-called “silent zone”, i.e. the region between the cone and the Mach disk, where the ions and gas molecules move at the same speed and direction into the vacuum system, while experiencing a strong cooling effect. The location of the Mach disk is described in relation to the cone (according to Equation 24), where \(X_M\) is the distance beyond the cone:

\[
X_M = \frac{0.67D_0}{P_0} \left( \frac{P_1}{P_0} \right)^{1/2}
\]

where \(D_0\) is the diameter of the cone orifice, \(P_0\) is the pressure on the entrance side of the cone, and \(P_1\) is the pressure on the vacuum side of the cone. The entrance of the skimmer (typically ~1.4–0.6 mm in diameter) immediately following the cone (~0.3–0.5 mm in diameter) should be positioned so that sampling of the molecular beam occurs inside the silent zone of the free jet expansion (Figure 13b), where the transmission of ions through the skimmer is most efficient.

Accompanying expansion into the vacuum, of course, is considerable cooling and hence a tendency for condensation, especially if water molecules are present. However, the condensation can be inhibited via the use of a so-called “curtain gas” that is directed across the front of the cone (Sciex), or a counter-current flow of drying gas that is sometimes heated (Analytica of Branford). The pressure in the region between cone and skimmer is around 10\(^{-2}\) Torr; thus the mean free path of movement of an ion is sufficiently long that acceleration of ions between the cone and skimmer will cause energetic collisions between ions and residual gas molecules, resulting in fragmentation. The level of fragmentation can be controlled to some degree by varying the potential difference between the cone and the skimmer (effectively changing the velocity of the ions undergoing collision). This CID process, referred to as “in-source CID” or “nozzle-skimmer CID”, should not be confused with CID occurring in a collision cell or trapped ion region of a tandem mass spectrometer. Mild (low-energy) “in-source CID” can be used to break up the remaining cluster ions. For each type of counter-electrode, be it a cone-shaped orifice or a tube, the build-up of contaminants on the counter-electrode over time can block the orifice, thus necessitating frequent cleaning; well-designed systems allow for easy removal and cleaning.
2.3 The Electrospray Ionization Mass Spectrum

The above discussion has centered upon a description of how ions are transferred from solution into the gas phase during the ESI process. We now turn to a consideration of factors that influence the appearance of the ESI mass spectrum. Two characteristics that we will examine are: the factors that determine relative intensities of peaks in the mass spectrum; and those that influence the distribution of charge states when multiple charging is occurring. The ability to form ions characterized by very high charge states is unique, among ionization methods, to ESI.

2.3.1 Signal Suppression

Characterization of the relationship between ion abundance (i.e. signal response) and analyte concentration is an important factor in the understanding of any technique of solution analysis. Even under the best of circumstances, the solution containing even a purified analyte that is subjected to electrospray conditions cannot be considered to be a “single electrolyte” system. Electrochemical reactions occurring at the ESI capillary alter the solution composition, and impurities can enter from a variety of sources, including via reagent-grade solvents (e.g. methanol, water, acetonitrile) that often contain $\sim 10^{-5}$ M Na$^+$, and via contamination of the capillary line and fittings leading all the way up to the spray tip. Moreover, electrolytes are often added to sample solutions to improve the production of specific types of ions, e.g. acid is commonly added to promote the formation of MH$^+$, whereas base is sometimes added to increase [M − H]$^-$ production in negative ion ESI. In considering a solution containing analyte A in the presence of added electrolyte B and impurity C, the total electrospray current, $I_{\text{total}}$, is given by the sum of the signals given by the three constituents $I_A + I_B + I_C$ (Equation 25).$^{114,115}$ The signal from the analyte, $I_A$, is given by Equation (26):

$$I_{\text{total}} = I_A + I_B + I_C$$

$$I_A = \frac{fpI_{\text{total}}k_A[A^+]}{k_A[A^+] + k_B[B^+] + k_C[C^+]}$$

where $k_A$, $k_B$, and $k_C$ are the corresponding rate constants for desorption of analyte A, added electrolyte B and impurity C, $f$ is the fraction of the total charges on all droplets that are transferred to gas-phase ions, and $p$ is the ion-sampling efficiency, i.e. the fraction of formed gas-phase ions that reach the detector. The characteristics of the specific species undergoing desorption determine the value of the desorption rate constants. Species with relatively high surface activities will have higher desorption rate constants, and will thus exhibit an increased tendency to produce signal.$^{114,115}$

From Equation (26) it can be seen that the intensity of the peak for analyte A is determined not only by its desorption rate constant and concentration but also by the concentrations and characteristics of the electrolytes present, be they intentionally added or entering as impurities. This description is consistent with experimental results.$^{81}$ In practical terms, the implication is that electrolytes present in solution effectively suppress analyte signals, and hence solutions containing high concentration electrolytes should be avoided.$^{116}$ Analyte signal suppression from competing analytes turns out to be one of the largest shortcomings of ESI/MS and it can be a prohibitive factor for the successful analyses of complex mixtures, especially when the compounds of interest are present at trace levels.

2.3.2 Linearity and Dynamic Range

Even in the presence of competing electrolytes, the signal produced by a given analyte exhibits a linear dependence.
on concentration over a certain “linear dynamic range” that can extend from the lower limit of detection (often below $10^{-12}$ M) up to $\sim 10^{-5}$ M.\(^\text{110,117}\) Over this range, in favorable cases, the analyte signal increases linearly with concentration. Above the upper limit of $\sim 10^{-5}$ M, it is postulated that insufficient charge is present to create ionic species out of all analyte molecules.\(^\text{115}\) As elaborated above, signal response is affected by competition for available charge with other solution species. Sensitivity is also a function of solvent composition, flow rate, and characteristics of the analyte itself, such as its surface activity. Highly surface-active analytes have lower limits of detection. Of course, the ability to create ionic form(s) of the analyte in solution is also important, whether through protonation/deprotonation, adduct formation with small solution cations/anions, or ionization via electrochemical oxidation/reduction processes. Different chemical structures will have different rate constants for ion desorption. For the purposes of quantitation, knowledge of the linear dynamic range can be of key importance. The expansion of the linear dynamic range is of practical significance for the pharmaceutical industry and many other fields. As noted above, low flow rates can increase the overall ionization efficiency and thereby improve detection sensitivities, allowing the attainment of detection limits in favorable cases in the attomole ($10^{-18}$ mol) range.\(^\text{105,106}\)

### 2.3.3 Charge State Distributions

Among all the mass spectrometric ionization techniques, the ability to form multiply charged analyte ions of very high charge states is unique to the ESI process. Multiple charging in the positive ion mode usually occurs via multiple protonations of analyte ions, such as proteins. In the negative ion mode, multiple deprotonation (i.e. multiple H\(^+\) dissociations) is usually occurring in order to produce anions of high charge states. The result is that the mass spectrum of a “pure” compound exhibits a series of peaks that are all representative of intact molecules that differ in the number of charges that they carry. Adjacent peaks in the characteristic “envelope” of ions constituting the mass spectrum of a protein or other multiply charged molecule (Figure 14) progressively contain one less charge as one moves toward higher $m/z$ values in the spectrum.

The appearance of the envelope, including the range of charge states observed, and the most intense peak in the mass spectrum, as well as the relative intensities of other peaks, depend upon a combination of factors. Parameters that affect the so-called “charge state distribution” of a given analyte include characteristics of the molecule such as structure, conformation, and concentration. In addition, solution conditions such as equilibrium considerations and solvent polarity, as well as experimental parameters particular to a given mass spectral acquisition, will influence the distribution of charge states observed in the ESI mass spectrum.

#### 2.3.3.1 Effect of Analyte Structure

An obvious structural feature that has a profound effect on the charge state distribution is the number of available sites for protonation/deprotonation on the analyte molecule. Early reports on the multiple charging phenomenon correlated the number of basic sites on protein molecules to the number of charges (protons) that could attach and were retained on analyte molecules in obtained ESI mass spectra.\(^\text{118–121}\) Another structural feature that has a strong influence on the propensity for charge attachment onto proteins is the tertiary structure (conformation) of

![Figure 14](image.png) Positive ion ESI mass spectrum of equine cytochrome c. All peaks are representative of intact cytochrome c molecules, with different charge states (varying numbers of protons attached).
the protein.\textsuperscript{119,122} A native protein with a tightly folded conformation (e.g., a protein that has multiple disulfide bonds) may "bury" some of the ionizable sites in a relatively hydrophobic interior of the folded molecule. A site which otherwise might carry a charge is thus rendered neutral, and protonation/deprotonation on peripheral sites of the molecule might contribute further to shielding the charge attachment/departure at the interior site. This would result in a shift in the charge state distribution toward lower values. Indeed, the observed maximum charge states are much lower than predicted by the number of basic sites for certain proteins containing multiple cysteine–cysteine disulfide bonds.\textsuperscript{119}

For a protein that has undergone denaturation (via heat, or via chemical reduction of the disulfide bond), the biopolymer can become fully extended. Because sites that were previously shielded to charging become exposed, such denaturation often results in a shifting of observed charge states toward higher values.\textsuperscript{119,121–124} One example is hen egg-white lysozyme, which shows a maximum charge state of 14; however, upon the addition of dithiothreitol, the maximum charge state observed in the ESI mass spectrum shifts to a value of 20. This latter number of attached protons corresponds to the total number of basic sites on the protein.\textsuperscript{119}

\subsection*{2.3.3.2 Effect of Analyte Concentration}
A varying concentration of the analyte can also change the charge state distribution.\textsuperscript{125} At higher concentrations there are more analyte molecules competing for a limited number of excess charges in a droplet, which implies that the charge state distribution will shift toward lower values as compared to lower-concentration solutions.\textsuperscript{126} This analysis implies that different charge-state ions of the same analyte may have different response vs concentration characteristics, including different linear dynamic ranges and even different slopes in the linear range. Thus, appropriate caution is due when evaluating the concentration dependencies of signals arising from multiply charged analytes.

A mathematical treatment (see Equation 27) has been used to evaluate how many excess charges are available per analyte molecule as a function of analyte concentration, where \(N/N_0\) represents the ratio of the total number of excess charges \(N\) to the total number of analyte molecules present \(N_0\) in the droplets:\textsuperscript{125}

\[
\frac{N}{N_0} = \frac{I/e}{ACV_f} \tag{27}
\]

Here, \(I\) represents the current leaving the ESI capillary. When this is divided by \(e\), the elemental charge, one obtains the number of excess charges available. To obtain the total number of analyte molecules present in all droplets, one calculates the product \((ACV_f)\), where \(A\) is Avogadro’s number \((6.023 \times 10^{23} \text{ molecules mol}^{-1})\), \(C\) is the analyte concentration \((\text{mol L}^{-1})\), and \(V_f\) is the solution flow rate into the mass spectrometer \((\text{L s}^{-1})\). It was determined that as the analyte concentration was progressively raised, the value of \(N/N_0\) (representing the number of charges available per analyte molecule) decreased, as did the average observed charge state in the ESI mass spectrum.\textsuperscript{125}

\subsection*{2.3.3.3 Effect of Solution-phase Properties}

Multiply charged ions observed in ESI/MS arise from molecules that undergo either protonation/deprotonation or cation/anion attachment in the initial "neutral solution" or during the ESI process. Therefore, it is reasonable to presume that solution-phase equilibria considerations, which are affected by the choice of solvent, pH, and electrolyte concentration, will have an effect on the charge state distribution of generated gas-phase ions.

The characteristics of the solvent influence the formation of gas-phase ions in a variety of ways. For example, the onset voltage for electrospray (i.e., the minimum potential required to form the Taylor cone) will increase with the surface tension of the solution, the spray current will increase with solution conductivity, and the initial droplet size will increase with solvent viscosity.\textsuperscript{73} Higher solvent polarity also shifts the dissociation equilibrium to favor the formation of higher charge-state ions in solution (see Equations 28 and 29), thereby favoring the formation of more highly charged ions in the gas phase.

\[
AB_2 = AB^- + B^+ \tag{28}
\]

\[
AB^- = A^2^- + B^+ \tag{29}
\]

Both of these dissociation equilibria shift to the right as the solvent polarity is increased, which has the effect of increasing the concentrations of species of higher charge states. Raising the solvent polarity was shown to produce higher charge states of analyte ions in ESI/MS experiments conducted in both the negative ion\textsuperscript{127} and the positive ion\textsuperscript{128} modes.

Another solution property that will affect the acid–base equilibrium dramatically is solution pH. For the determination of proteins, Chowdhury et al.\textsuperscript{122} observed that the lowering of pH below a critical threshold (corresponding to the acidity where denaturation takes place) resulted in a sudden dramatic shift in charge states observed in the ESI mass spectrum. As outlined above, the protein was capable of acquiring a significantly higher level of charge as soon as it became unfolded, but separate experiments revealed that for the relatively rigid structures of the peptides bradykinin and gramicidin S only minor shifts in the charge state distributions occurred as the hydronium ion concentration was varied by seven orders of magnitude.\textsuperscript{129} This latter result clearly revealed the
discrepancy between solution-phase equilibria and charge states observed in ESI mass spectra.

Evidence has emerged that electrolytes present in solution, especially the counter-ions associated with charged sites on the molecule, can have an important influence on the observed distribution of charge states of gas-phase ions. Mirza and Chait\textsuperscript{130} reported that the different nature of counter-ions present would shift the analyte charge state to different degrees. When present, the following anions were observed to shift charge state distributions to lower values, but by progressively decreasing amounts: $\text{CCl}_2\text{COO}^- > \text{CF}_2\text{COO}^- > \text{CH}_3\text{COO}^- \sim \text{Cl}^-$. This type of shift, however, was corroborated\textsuperscript{116} to be quite variable and dependent upon the level of interaction between the counter-ion and the analyte under investigation, with certain electrolyte–analyte combinations being quite resistant to any shift.

Fenselau and co-workers\textsuperscript{131} examined positive and negative ion ESI mass spectra of myoglobin at varying pH. They reported that for basic solutions (pH 10), where minimal solution-phase protonation was occurring, in positive ion ESI an envelope of multiply charged ions with a maximum charge state of +14 was observed, corresponding to multiply protonated myoglobin. This result is not expected because at pH 10 myoglobin exists virtually exclusively in anionic form in solution. Moreover, at an acidic pH of 3, in the negative ion mode an envelope of multiply deprotonated myoglobin molecules was observed, having a maximum charge state of −11, even though myoglobin exists virtually completely in cationic form in solutions of pH 3.

In order to explain the production of positively charged proteins in basic solutions to which nitrogen bases had been added, Le Blanc et al.\textsuperscript{132} proposed that the multiply protonated proteins were desorbed with the nitrogen bases attached. These complexes might then dissociate in the gas phase, resulting in the partitioning of available charge (protons) between the polypeptide and the nitrogen base. This explanation was used to rationalize an observed shift in charge states toward lower values in the ESI mass spectrum obtained from a solution containing a nitrogen base as compared to that of an otherwise identical solution devoid of base. More recently, Boyd and co-workers\textsuperscript{133} have rationalized the appearance of protonated molecules (MH$^+$) in ESI mass spectra obtained from highly basic solutions where initial solution protonation of the analyte molecules was negligible. The solution pH was raised via addition of tetramethylammonium hydroxide, an electrolyte that cannot be considered to be a source of protons. A mechanism was proposed whereby tetramethylammonium cations react with water (solvent) to liberate protons from water. These protons of solvent origin attach to analyte molecules as desolvation reaches completion, thus accounting for the multiply protonated molecules that arise from highly basic solutions where initial solution protonation is negligible.

2.3.3.4 Effect of Instrumental Conditions

Obtained charge state distributions in ESI/MS are also affected, either subtly or substantially, by instrumental factors such as ion source configuration, counter-current drying gas and cooling gas flow rates, as well as the cone voltage. The design of the ion source will determine the thermal energy and time available for desolvation.\textsuperscript{134} In the desolvation step, solvent can depart carrying some of the available excess charges. This process can effectively shift the charge state distributions of analyte ions toward lower values. When the flow rate of heated counter-current drying gas was increased, thus increasing the droplet evaporation rate, charge states shifted to higher values.\textsuperscript{193} Moreover, an increase in the source temperature would have a similar effect and can therefore increase charge state values.

Another instrumental factor that exerts a large influence on charge state distributions is the cone voltage, which determines the level of “in-source” CID. For gas-phase ions, the cone serves both as an electrostatic lens and as an accelerator of ions. The velocity of ions in the region just after the cone is determined largely by the voltage drop between the cone and the ensuing skimmer. An elevated cone voltage results in more energetic collisions between ions and the neutral gas molecules present, which induces a higher degree of decomposition. Collisions are most efficient at producing dissociation when the pressure is low enough such that an ion has a significant mean free path of travel before colliding into a gas molecule, yet high enough such that the probability of collision is still significant. An elevated cone voltage implies a high translation energy for the ions, resulting in a high uptake of internal energy upon collision. Higher charge-state ions of a given molecule will be accelerated to a greater degree than lower charge-state counterparts, and it is likely that higher charge-state ions will also undergo desolvation at a slower rate. A higher charge state also implies a higher propensity toward reaction, because the number of reactive charge sites is increased and the Coulomb energy is higher. These factors result in an increased tendency for higher charge-state ions to lose charges (via transfer to residual solvent, other solution components, or residual gases). Thus, an increasing cone voltage leads to a shift toward lower charge-state ions in the ESI mass spectrum.\textsuperscript{113}

2.3.3.5 Effect of Gas-phase Processes

The last factor to be described here that affects the charge state distribution is proton transfer reactions that occur in the gas phase. McLuckey et al.\textsuperscript{135,136} demonstrated that dimethylamine would react with multiply charged...
transform ion cyclotron resonance/MS). Oligonucleotide mapping/sequencing and fragmentation have also been studied intensively by electrospray ionization/tandem mass spectrometry (ESI/MS/MS).\(^{146-150}\) Protocols have been developed for the detection of modified nucleosides, such as those arising from endonuclease digests of RNA\(^{151}\) and DNA.\(^{152,153}\) Noncovalent interactions of nucleic acids have also been studied successfully by ESI/MS,\(^{148}\) including nucleic acid–nucleic acid, nucleic acid–protein, and nucleic acid–small molecule interactions. ESI/MS has been applied to the determination of products from polymerase chain reactions of DNA samples.\(^{154,155}\)

### 2.4 Applications

The inherent feature of producing gaseous ions from ions in the solution phase has led to a wide variety of application areas, especially in the biological sciences. Given below are brief summaries of the major application areas of ESI/MS (see Table 6).

#### 2.4.1 Electrospray Ionization Mass Spectrometry of Peptides and Proteins

ESI/MS has been applied successfully to the determination of primary protein structures, including molecular weight determinations and peptide mapping, via tandem MS. In addition, protein conformation\(^{77,78,119,121,122,144,145}\) and a variety of noncovalent protein complexes,\(^{77,78}\) such as protein–peptide, protein–metal, protein–small molecule, protein–subunit, and protein–nucleic acid, have been studied intensively.

#### 2.4.2 Electrospray Ionization Mass Spectrometry of Nucleic Acids

The determination of molecular weights allows one to deduce the compositions of nucleic acids having lengths up to 14-mers, or up to 25-mers if one has access to a greater degree of mass accuracy (e.g. using Fourier transform ion cyclotron resonance/MS). Oligonucleotide mapping/sequencing and fragmentation have also been studied intensively by electrospray ionization/tandem mass spectrometry (ESI/MS/MS).\(^{146-150}\) Protocols have been developed for the detection of modified nucleosides, such as those arising from endonuclease digests of RNA\(^{151}\) and DNA.\(^{152,153}\) Noncovalent interactions of nucleic acids have also been studied successfully by ESI/MS,\(^{148}\) including nucleic acid–nucleic acid, nucleic acid–protein, and nucleic acid–small molecule interactions. ESI/MS has been applied to the determination of products from polymerase chain reactions of DNA samples.\(^{154,155}\)

#### 2.4.3 Electrospray Ionization Mass Spectrometry of Carbohydrates and Lipids

Both derivatized and underivatized carbohydrates and lipids can be investigated by ESI/MS.\(^{156-158}\) Neutral oligosaccharides have been observed as sodiated ions rather than protonated ions in the positive ion mode, due to the stronger tendency for Na\(^+\) addition. Other metal cations have also been observed to form adducts in positive ion ESI/MS, such as Ca\(^{2+}\) and Mg\(^{2+}\) for oligosaccharides.\(^{159}\) However, in the negative ion mode, glycoconjugates display the unusual features of chloride attachment in the presence of chlorinated solvents,\(^{161-162}\) and C\(_2\)H\(_4\)O\(_2\)\(^-\) attachment in the presence of methanol.\(^{161}\) Acidic glycoconjugates such as gangliosides,\(^{156}\) sulfated Lewis-type oligosaccharides,\(^{163}\) phospholipids,\(^{164}\) acylglycerols,\(^{165}\) lipid A,\(^{166,167}\) and glycosylphosphatidylinositols\(^{168}\) have also been investigated in both positive and negative ion modes; however, negative ion ESI/MS generally exhibits higher sensitivity for acidic glycoconjugates.\(^{157,169}\)

#### 2.4.4 Electrospray Ionization Mass Spectrometry of Drug Metabolites and Pharmacokinetics

ESI/MS has been widely used to determine drug metabolites in biological fluids when a mixture of radioactive isotope-labeled and normal parent drugs is employed.\(^{170,171}\) A mass profile, containing both radiolabeled and non-radiolabeled pseudomolecular ions, reveals all the compounds representing metabolites of the parent drug derived from biodegradation and biosynthesis processes. LC with ESI/MS/MS\(^{166}\) and capillary electrophoresis with ESI/MS\(^{168,79,172}\) are well-established techniques for the isolation and determination of drug metabolites, as well as pharmacokinetics.\(^{173}\)

#### 2.4.5 Electrospray Ionization Mass Spectrometry of Inorganic and Organometallic Complexes

Study of inorganic and organometallic complexes by ESI/MS has also received a high level of attention.\(^{174-179}\)

### Table 6 Summary of applications of ESI/MS

Many inorganic or organometallic compounds can form ions in solution that are amenable to ESI determination, such as solvated metal ions, \[(174,175)\] metal oxides, \[(180)\] metal oxo ions, \[(181)\] polyoxoanions, \[(182)\] organoarsenics, \[(183)\] and lanthanide metal ions, \[(176,184)\] ESI/MS also presents a new research area for coordination chemistry, namely the study of gas-phase metal complexes that have been studied previously only in solution phase. The inherent soft ionization character of ESI allows the structural determination of a variety of complexes of metals with various entities such as proteins and peptides, amino acids, nucleic acids, carbohydrates, as well as the characterization of supermolecular complexes.

### 3 SUMMARY

The API techniques of APCI and ESI represent valuable and convenient means of creating gas-phase ions out of analytes dissolved in solution. Coupling of these ionization techniques to virtually all types of mass spectrometers (quadrupole, magnetic sector, time-of-flight, quadrupole ion trap, Fourier transform ion cyclotron resonance) is at an advanced state. Both techniques are extremely well suited for on-line coupling to liquid chromatographs, and it is fair to say that these are the two preferred mass spectrometric ionization methods for LC/MS experiments. Moreover, the types of compounds for which one would tend to choose LC as a preferred separation method (i.e. moderately polar, thermally labile compounds) often have the types of molecules that are ionized most efficiently by APCI and ESI. Thus, both APCI/MS and ESI/MS are considered to offer extremely high sensitivities for the analysis of polar molecules, with ESI performing somewhat better for very large, highly polar, and ionic compounds, whereas APCI offers certain advantages for lower-polarity analytes. Both APCI and ESI are considered to be “soft” ionization techniques that yield predominantly ionic forms of intact molecules. ESI is so gentle that it allows the investigation of weak (non-covalent) solution-phase interactions with the least perturbation during the transfer into the gas phase. These examples prove that both APCI and ESI are established, indispensable tools in the MS arsenal.

Chemical ionization mass spectrometry (CIMS) is a technique for forming ions of the compound of interest (analyte, A) by ion/molecule reactions from reactant ions of a reagent gas that is generally present in a much greater abundance than the analyte. The reactant ions are generally produced by electron ionization (EI) of the reagent gas. The ions produced by EI often react with the large excess of the reagent gas to form the actual reagent ions that react with the analyte. CIMS is performed with both positively and negatively charged reactant ions. The most common ion/molecule reactions in CIMS are proton transfer (which forms AH⁺ or [A – H]⁻ ions), hydride transfer (which forms [A – H]⁺ ions), charge or electron transfer (which forms A⁺⁺ or A⁻⁻ ions), and adduct formation or attachment (which forms [A + R]⁺ or [A + R]⁻ ions). Fragment ions from decompositions of these AH⁺, A⁺⁺, [A – H]⁻, and [A + R]⁺ ions are frequently observed. The extent of fragmentation can be controlled by the choice of reagent gas used and can be predicted to some extent from ionic thermochemical data. Collisionally stabilized electron capture at high pressures (to form A⁺⁺ ions) is often classified as chemical ionization (CI). The most common use of CIMS in analytical mass spectrometry is to obtain simplified mass spectra of compounds, often one species spectra, which can be used for quantitative analysis of mixtures. CIMS can be performed with any type of mass spectrometer (quadrupole, magnetic, time-of-flight (TOF), Fourier transform ion cyclotron resonance (FTICR), ion trap) and CIMS capabilities are routinely available on many commercial instruments. With ion trap or FTICR mass spectrometers, it is possible to select specific reactant ions. It is generally considered that CI and EI sensitivities are approximately the same in the positive ion mode and that electron capture CI at high pressures for compounds with high electronegativities gives a much greater sensitivity than other EI or CI techniques. CIMS has the same general limitations as electron ionization mass spectrometry (EIMS) on the volatility and thermal stability of the compound being analyzed. However, direct insertion of the sample into the source of the mass spectrometer allows the analysis of relatively involatile and thermally unstable compounds.

1 INTRODUCTION

CIMS is an analytical application of ion/molecule reactions. This analytical technique is an outgrowth of studies of ion/molecule reactions at high (~2 torr) pressures in the source of a mass spectrometer, when it was observed that the distribution of ions in methane was very sensitive to very small amounts of water and ethane. The sensitivity of ionic composition in gases to trace impurities was established many years ago in drift velocity experiments. Subsequent experiments on mixtures of CH₄ with small amounts (~1%) of other compounds showed the rapid reactions of CH₃⁺ and C₂H₅⁺ (the major ions in methane) to form ions characteristic of the added compounds.
CI was introduced shortly thereafter with a comparison of the ions produced from ion/molecule reactions of CH$_3^+$ and C$_2$H$_5^+$ with compounds (their CI spectra) and the EI spectra of these compounds.$^{(9)}$ The CI spectra showed enhanced abundances of ions in the molecular weight region, [M ± H]$^+$, compared with the EI spectra, [M$^{+\#}$], which aided in the molecular weight determination and identification of these compounds. The formation of the fragment ions could generally be explained by proton or hydride transfer followed by simple cleavage or rearrangement decompositions, and quantitative analysis was demonstrated for a simple mixture of alkanes.$^{(5)}$ The use of CIMS received a big boost a few years later by work demonstrating the usefulness of the technique for the analysis of complex molecules of biomedical interest: “The biologically important ethanolamine, ephedrine, is a substituted benzyl alcohol and thus the absence of a molecular ion in its EI mass spectrum is not surprising. The CI mass spectrum on the other hand could stand alone as a complete structure proof.”$^{(6)}$

One common use of CIMS is illustrated by the analysis of cholesterol esters of fatty acids. The EI mass spectra of cholesterol esters are very complex, containing many fragment ions with roughly equal abundances and no M$^{+\#}$ ions. The $i$-C$_{4}$H$_{10}$ CI mass spectra, on the other hand, were reported to be essentially two species spectra: the cholesteryl ion at m/z 369 and the protonated acids.$^{(7)}$ Thus, one could easily identify the components in a mixture without prior separation. The simplicity of $i$-C$_{4}$H$_{10}$ CI mass spectra and the high likelihood of obtaining MH$^+$ ions for each compound in a mixture were combined with collisionally induced dissociations (CID) to characterize components in a complex mixture (nutmeg) without chromatographic separations.$^{(8)}$

One illustration of the selectivity of the technique is shown in an analysis of polymer additives by vaporization from a polypropylene sample directly into the source of a mass spectrometer using a CH$_4$/1% NH$_3$ mixture as the reagent gas.$^{(9)}$ In these experiments the polar high molecular weight additives were detected as MH$^+$ or [M + NH$_4$]$^{+\#}$ ions and hydrocarbons from the polymer were not detected. The methane/ammonia spectra generally contained only one major ion and quantitative analyses could be obtained from the integrated area as the polymer additive was driven from the sample by heating. The additives could be identified from a small set of likely compounds by the molecular weight and CH$_4$ CI or EI spectra could be obtained for further confirmation.

It is generally considered that the sensitivities in positive and negative ion CI are approximately the same, and approximately the same as the sensitivities for the same compounds in EI because the rate constants for positively and negatively charged ions with neutral molecules are generally comparable in magnitude.$^{(10,11)}$ Negative ion CIMS by definition refers to negative ions produced by reactions of negatively charged reactant ions with the analyte; however, the mechanism of formation of the negative ions is not always well established and electron capture negative ion spectra are obtained at high pressures with compounds of high electron affinities. Negative ion sensitivities for certain compounds containing highly electron-negative groups have been reported to be 100–1000 times as high as positive ion sensitivities.$^{(12)}$

## 2 FUNDAMENTALS OF ION/MOLECULE REACTIONS

### 2.1 Historical Background

Ion/molecule reactions were observed, but not necessarily recognized as such, early in the development of mass spectrometry, primarily because of the difficulties in obtaining sufficiently low pressures that collisions between the ions and the large excess of un-ionized molecules would not occur within the ionization region (source) of the mass spectrometer. An ion at m/z 3 was reported by Thomson from bombardment of many solids with cathode rays and although he assigned the species as H$_3^+$, he did not develop a mechanism for its formation and perhaps considered H$_3$ to be a stable compound.$^{(13)}$

Subsequently Hogness and Lund reported an extensive study on the variation of the relative abundances of ions in H$_2$ as the pressure was increased at an essentially constant reaction time.$^{(14)}$ These data showed a decrease in the relative abundance of H$_2^{+\#}$ and a consequent increase in the relative abundance of H$_3^+$ with increasing pressure. These observations definitively established the following reactions (Equations 1 and 2) for the formation of H$_3^+$,

\[
H_2 + e^- \rightarrow H_2^{+\#} + 2e^- \quad (1)
\]

\[
H_2^{+\#} + H_2 \rightarrow H_3^{+\#} + H^+ \quad (2)
\]

These pressure plots represent the type of experiments that were done to study ion/molecule reactions in many of the early investigations into ion/molecule reactions. Any ion whose relative abundance increased with increasing pressure was at least partially formed by ion/molecule reactions. If the reactions could be studied to a large extent of conversion (as in this case), any ion whose relative abundance decreased with increasing pressure reacted in an ion/molecule reaction.

H$_3^+$ had one important use in the mass spectrography for the determination of the accurate atomic weight of deuterium. “The packing fraction of H$_2$, which is clearly of the greatest interest in connection with the structure
of its nucleus, has been measured... between the line of helium and that of the triatomic molecule \( H_2^1H^1H^2 \) obtained from the discharge in hydrogen enriched by distillation.*\(^{(15)}\)

### 2.2 Incidental Observations of Ion/Molecule Reactions

There were few studies of ion/molecule reactions during the 1930s and 1940s and the primary research emphasis was on ionization processes. The vacuum technology was improved so that pressures and frequencies of collisions of ions with molecules in the ionization region were much lower. Pyrolysis products from the hot wire filaments no longer contaminated the source. An ion at \( m/z \) 19, \( H_3^1O^+ \), was observed in experiments with water, and pressure studies showed that it was formed by a second-order process, that is, \( I(19)/I(18) \) increased with increasing pressure of water in the mass spectrometer (as noted in section 2.1 for \( H_2^1 + ^H_2^2^+ \)).\(^{(16)}\) The \( H_2O \) system contains two abundant ions from EI, \( H_2O^+ \) and \( HO^+ \); so that a simple pressure study over a small pressure range would not establish which of the two ions was the reactant. Appearance potential measurements indicated that the minimum energy for the formation of \( H_2O^+ \) was approximately the same as the ionization potential (IP) of \( H_2O \) and significantly below the minimum energy for the formation of \( HO^+ \) from water.\(^{(16)}\) Consequently, the reactions for the formation of \( H_3^1O^+ \) are Equations (3) and (4):

\[
\begin{align*}
H_2O + e^- &\rightarrow H_2O^+^+ + 2e^- \quad (3) \\
H_2O^+^+ + H_2O &\rightarrow H_3O^+ + HO^+ \quad (4)
\end{align*}
\]

The use of ionization and appearance potential measurements has been critical in the determination of reactant/product sequences for ion/molecule reactions.

Analytical mass spectrometry and commercial mass spectrometers were developed in the 1940s and used extensively in the petroleum industry for the quantitative analysis of mixtures of light hydrocarbons.\(^{(17,18)}\) Pressures in these instruments were maintained at low values and the experimental conditions were generally standardized to eliminate ion/molecule reactions as complications for quantitative analyses and the determination of isotopic abundances.

Occasional observations of ion/molecule reactions were made, which demonstrate the care that was used in most experiments to eliminate these processes. The determination of \( ^13C \) in organic compounds is generally done by measuring the \( I(45)/I(44) \) ratio in \( CO_2 \) after combustion of the samples. It was noted that if \( H_2O \) was not eliminated from the combustion products the \( I(45)/I(44) \) ratio was abnormally large and increased with increasing sample size: clear indications of ion/molecule reactions.\(^{(19)}\) As mass spectrometers became more common and were being used for qualitative analysis and identification of compounds in addition to quantitative analyses of known mixtures, ions were observed at masses larger than the presumed molecular weights of the compounds being introduced. These observations were useful for the determination of molecular weights of polar compounds (such as esters and ethers) whose EI spectra contained essentially no \( M^+ \) ions.\(^{(20,21)}\) Formation of \( MH^+ \) ions from reactions of fragment ions of the sample with the neutral sample molecules is now often called ‘self-CI’.

### 2.3 Reactions of Ions in Methane

The modern work on ion/molecule reactions is continuous from the experiments in the 1950s. Three groups were heavily involved in this work: Tal’roze in the Soviet Union; Stevenson and Schissler at Shell Oil; and Field, Franklin, and Lampe at Humble Oil (Esso).\(^{(22–24)}\) Tal’roze and Ljubimova’s experiments showed that the ratio, \( I(17)/I(16) \), increased with increasing pressure of methane in the source from the correct isotopic value of 1.1% to ~3% at the highest pressures used. In addition, the appearance potential for \( CH_4^+ \) and the IP of \( CH_4 \) were the same within experimental precision.\(^{(22)}\) Consequently, the following reaction sequence was established, (Equations 5 and 6):

\[
\begin{align*}
CH_4 + e^- &\rightarrow CH_4^{++} + 2e^- \quad (5) \\
CH_4^{++} + CH_4 &\rightarrow CH_5^+ + CH_3^+ \quad (6)
\end{align*}
\]

Rate constants were measured for Equation (6) and some simple ion/molecule reactions, including the other major ion/molecule reaction in methane, (Equation 7):

\[
CH_3^+ + CH_4 \rightarrow C_2H_5^+ + H_2 \quad (7)
\]

and it was observed that the reactions which could be observed at the low source pressures (~0.001 mmHg) and short times (microseconds) that were accessible at that time were all very fast, with rate constants \(~1 \times 10^{-9} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} \) (~6 \times 10^{20} \text{ L mol}^{-1} \text{ s}^{-1}).\(^{(23,24)}\) These rate constants correspond to reactions which occur at essentially every collision.

### 2.4 Ion Chemistry of \( CH_3^+ \) and \( C_2H_5^+ \)

The experiments in the 1950s that re-established the occurrence of fast ion/molecule reactions were generally done with conventional mass spectrometers that had been modified to allow operation at slightly higher pressures. However, the pressures were not sufficiently high that significant conversions of reactant ions to product ions could be seen. Subsequently, high-pressure mass spectrometers were developed which could operate at source pressures of a few torr.
It was shown with ultra high purity methane that neither \( \text{CH}_3^+ \) nor \( \text{C}_2\text{H}_5^+ \) reacted at a significant rate with methane to produce new product ions.\(^{(1)}\) Experimentally, the relative abundances of \( \text{CH}_3^+ \) and \( \text{C}_2\text{H}_5^+ \) reached constant values as the pressure was increased. Subsequently, the nonreactivity of \( \text{CH}_3^+ \) and \( \text{C}_2\text{H}_5^+ \) with methane was confirmed by ion cyclotron resonance (ICR) experiments at very low pressures and long reaction times.\(^{(25)}\)

A kinetic analysis shows that the rate expressions contain a term that is the product of concentration of neutral molecules and the ionic reaction time. CIMS experiments at high pressures and short times and Fourier transform ion cyclotron resonance/mass spectrometry (FTICR/MS) experiments at low pressures and long reaction times have approximately the same value for this product, \([X]t \sim 10^{-6}\) torr sec.

Since neither \( \text{CH}_3^+ \) nor \( \text{C}_2\text{H}_5^+ \) reacted with methane, it was possible to study the reactions of \( \text{CH}_5^+ \) and \( \text{C}_2\text{H}_5^+ \) with other compounds by adding a small amount (<1%) of the other compounds to methane and observing the effects on the relative abundances of \( \text{CH}_3^+ \) and \( \text{C}_2\text{H}_5^+ \). As noted in section 2.1, any ion that reacts by an ion/molecule reaction will decrease in relative abundance as the pressure (and number of collisions) increases. Consequently, reaction of \( \text{CH}_3^+ \) or \( \text{C}_2\text{H}_5^+ \) is indicated by a maximum in the relative abundance of either ion as the pressure of a mixture of constant composition is increased and the product ions can easily be identified by mass. The kinetic analysis of this system is essentially the same as that of the consecutive radioactive decay scheme, \( \text{A} \rightarrow \text{B} \rightarrow \text{C} \). Analogous experiments were done at low pressures and long times characteristic of ICR experiments with similar results.\(^{(25)}\)

It was shown that \( \text{CH}_3^+ \) reacted by proton transfer, acting as a Brønsted acid. There was often extensive decomposition of the AH\(^+\) ions of the added substances because \( \text{CH}_3^+ \) is a strong acid (\( \text{CH}_4 \) is a weak base) and the AH\(^{**}\) ions are formed with sufficient internal energy that they may decompose. \( \text{C}_2\text{H}_5^+ \) reacted by both proton transfer (a less exothermic reaction than proton transfer from \( \text{CH}_3^+ \)) and by hydride transfer, acting as a Lewis acid.\(^{(13,4,25,26)}\) Some addition ions were observed with unsaturated compounds, but the dominant product ions were MH\(^+\), \([\text{M}–\text{H}]^+\), and some fragment ions. Proton transfer and hydride transfer are the dominant reactions in \( \text{CH}_4 \) CI.

### 2.5 Thermochemical Kinetics

Since the ions from the analyte are formed by ion/molecule reactions, the rate constants for these ion/molecule reactions are critical in determining the sensitivity and selectivity in CI mass spectrometry. One can model the CI process as a reaction (Equation 8) of a reactant ion, \( \text{R}^+ \), with the analyte, \( \text{A} \), to give products, \( \text{P}_i^+ \):

\[
\text{R}^+ + \text{A} \rightarrow \sum \text{P}_i^+ + \sum \text{N}_i \tag{8}
\]

The rate expression for the formation of all the product ions is given in the usual way as Equation (9):

\[
\frac{d}{dt} \sum \text{[P}_i^+] = k[\text{R}^+][\text{A}] \tag{9}
\]

For a small extent of conversion of \( \text{R}^+ \) to product ions, \( \text{P}_i^+ \), (which is generally true in most CI experiments), one may approximate \([\text{R}^+]\) with \([\text{R}^+]_0\), the initial concentration of the reactant ion. Since the initial concentration of product ions is zero, one obtains the following simple relationship (Equation 10) between the concentrations of product ions, \( \text{[P}_i^+] \), and reactant ions, \( \text{[R}_i^+] \), and \( \text{[A]} \), with the rate constant, \( k \), and reaction time, \( \Delta t \):

\[
\sum \text{[P}_i^+] = k[\text{A}][\text{R}_j^+]_0\Delta t \tag{10}
\]

Consequently, one can see that a large rate constant will give a large current of analyte ions and a sensitive analysis and that a very small (or zero) rate constant will produce a few ions or no product ions at all. The sensitivities for CI reagent ions can be correlated with the rate constants for the reactions and the rate constants can be predicted to some extent from theoretical models.\(^{(10)}\)

It is one of the major postulates of ion/molecule reactions that endothermic reactions have an activation energy and will be slow and probably not observable under the normal CI conditions of a few collisions of the reactant ion with the analyte molecules. Consequently, one can achieve selectivity in CIMS by choosing a reactant ion which will not react in an exothermic reaction with one analyte (or class of analytes).

For proton transfer reactions, (Equation 11):

\[
\text{AH}^+ + \text{B} \rightarrow \text{BH}^+ + \text{A} \tag{11}
\]

one can show that the heat of reaction is given by the difference in proton affinities (PA) (or base strengths) of \( \text{A} \) and \( \text{B} \) (Equations 12 and 13):

\[
\Delta H^\circ(11) = \text{PA}(\text{A}) - \text{PA}(\text{B}) \tag{12}
\]

\[
\text{PA}(\text{X}) = \Delta H^\circ_\text{f}(\text{H}^+) + \Delta H^\circ_\text{f}(\text{X}) - \Delta H^\circ_\text{f}(\text{XH}^+) \tag{13}
\]

That is, the proton transfer reaction follows the usual rules of acid–base reactions: in an exothermic reaction, the stronger base accepts the proton from the conjugate acid of the weaker base.

For hydride transfer reactions, (Equation 14):

\[
\text{R}^+ + \text{NH} \rightarrow \text{RH} + \text{N}^+ \tag{14}
\]
one can show that the heat of reaction is determined by the difference in hydride affinities (HA) of the two ions,
\[ \Delta H^\circ(14) = \text{HA}(\text{N}^+) - \text{HA}(\text{R}^+) \]  
\[ \text{HA}(\text{X}^+) = \Delta H^\circ_0(\text{X}^+) + \Delta H^\circ_0(\text{H}^-) - \Delta H^\circ_0(\text{XH}) \]  

That is, in an exothermic reaction, the stronger Lewis acid abstracts a hydride ion from the conjugate base of the weaker Lewis acid.

From the acid strength of a protonating reactant ion, RH⁺, or the proton affinity of the conjugate base, R, and the proton affinity of the analyte A, one can determine whether the CI reaction,
\[ \text{RH}^+ + \text{A} \rightarrow \text{AH}^+ + \text{R}, \]  
will be exothermic and, therefore, most probably fast, or endothermic and, therefore, most probably slow (or essentially zero). Similarly from the Lewis acidities of the reactant ion, R⁺ and the analyte ion, A⁺, one can determine whether the CI reaction,
\[ \text{R}^+ + \text{AH} \rightarrow \text{A}^+ + \text{RH}, \]  
will be exothermic and fast or endothermic and slow. Some data on PAs and HAs are available for simple species, and one can often make reasonable guesses from chemical intuition about more complex molecules.

2.6 Instrumentation

CIMS can be done with any type of mass spectrometer. The ion source must be much tighter than a conventional EI source to allow high pressures in the ionization region and low pressures in the analyzer region. Small electron entrance and ion exit apertures are essential. All other connections must be very tight to reduce the leakage of gas from the source. The reactions that produce the analyte ions occur in the source of the mass spectrometer and are not dependent on the type of mass analysis that is used to detect the ions. Magnetic, TOF, and quadrupole mass spectrometers have been used in high pressure CIMS. Magnetic instruments operate with the source of the mass spectrometer at a potential that is well above (or below, for negative ions) ground. The pressure region for most CI experiments (a few tenths of a torr) is the region where electric discharges are the most common. However, by using appropriate restrictors in the inlet line for the CI reagent gas, a sufficiently large pressure drop can be achieved that discharges do not occur from the source through the reagent gas to ground. Very good differential pumping is necessary to allow the source to operate at high pressures without degrading the resolution of the instrument or causing significant amounts of collisionally induced decompositions in the flight path of the ions. CI, however, is a standard addition for modern commercial magnetic mass spectrometers.

Quadrupole mass spectrometers are somewhat more forgiving about pressure problems since the sources of the instruments are not at high voltage. The pathlength of the ions in the analyzer region is also shorter and the resolution is generally not sufficiently large that collisional broadening of the peaks will create problems in mass detection.

Ion trap mass spectrometers have been used for CI studies in a lower pressure region with success. FTICR mass spectrometers have also been used for CI studies in the ultra low pressure region. Both of these instruments have the advantage that the CI reactant ions can be individually selected, in contrast with high pressure instruments. That is, using an ion trap or FTICR mass spectrometer, one could obtain CI mass spectra from CH₅⁺ only, whereas with the high pressure instruments, one can only obtain CI spectra using both CH₅⁺ and C₂H₅⁺ ions.

3 METHANE AS A CHEMICAL IONIZATION REAGENT GAS

3.1 Ionic Reactions

Methane was the first CI reagent gas used and it is still used when one wants a nonselective reagent gas that will ionize all samples. The dominant ions in the EI mass spectrum of methane are CH₄⁺⁺ at m/z 16 (~50%) and CH₃⁺ at m/z 15 (~40%) and CH₂⁺⁺ at m/z 14 (~10%). These ions react with methane to form a set of ions (CH₃⁺⁺, C₂H₅⁺⁺, C₃H₅⁺⁺) that do not react with methane but react with the analyte (Equations 6, 7, 19 and 20):

\[ \text{CH}_4^{++} + \text{CH}_4 \rightarrow \text{CH}_5^{++} + \text{CH}_3^* \]  
\[ \text{CH}_3^{++} + \text{CH}_4 \rightarrow \text{C}_2\text{H}_5^{++} + \text{H}_2 \]  
\[ \text{CH}_2^{++} + \text{CH}_4 \rightarrow \text{C}_2\text{H}_3^{++} + \text{H}_2 + \text{H}^* \]  
\[ \text{C}_2\text{H}_3^{++} + \text{CH}_4 \rightarrow \text{C}_3\text{H}_5^{++} + \text{H}_2 \]  

The dominant reaction of CH₅⁺⁺ is proton transfer, generally with extensive dissociation because CH₄ is a very weak base (or CH₅⁺⁺ is a very strong gas-phase acid). The dissociation processes are the loss of H₂ and the loss of stable neutral fragments. Some of the initially protonated species may be stabilized by collision Equations (21–24):

\[ \text{CH}_5^{++} + \text{A} \rightarrow \text{AH}^{++} + \text{CH}_4 \]  
\[ \text{AH}^{++} \rightarrow [\text{A} - \text{H}]^+ + \text{H}_2 \]  
\[ \text{AH}^{++} \rightarrow [\text{A} - \text{Z}]^+ + \text{ZH} \]  
\[ \text{AH}^{++} + \text{CH}_4 \rightarrow \text{AH}^+ \]
C₂H₅⁺ will undergo similar dissociative proton transfer reactions, although the extent of decomposition of AH⁺⁺ will be less because C₂H₅⁺ is a weaker Brønsted acid than CH₃⁺ (C₂H₄ is a stronger base than CH₄). In addition, C₂H₅⁺ can react as a Lewis acid by H⁻ abstraction, and the intermediate complex can be stabilized by collisions Equations (25–27):

\[
\begin{align*}
C₂H₅⁺ + A &\rightarrow [A - H]^⁺ + C₂H₆ \quad (25) \\
C₂H₅⁺ + A &\rightarrow [A + C₂H₅]^⁺⁺ \quad (26) \\
[A + C₂H₅]^{++} + CH₄ &\rightarrow [A + C₂H₅^+] \quad (27)
\end{align*}
\]

C₃H₅⁺ undergoes similar reactions to form [M ± H]⁺ and [M + C₂H₅⁺] ions. Adduct ions are formed from both C₂H₅⁺ and C₃H₅⁺ in small amounts and with compounds containing sites of unsaturation.

Consequently, the CH₄ CI mass spectra of organic compounds are expected to contain [M ± H]⁺ and fragment ions and not the M⁺⁺ ions that are observed in EI spectra. Although the fragment ions are likely to be similar in mass and structure for both EI and CI mass spectra, they are produced by entirely different reactions. Only for compounds with very low IPs, IP(A) < IP(C₂H₅⁺), such as amines, are M⁺⁺ ions observed from charge exchange reactions of C₂H₅⁺.

The CH₄ CI mass spectra of n-alkanes give abundant [M – H]⁺ ions and approximately equal amounts of lower alkyl ions. It was suggested that this product distribution resulted from random attack at the different methylene sites followed by localized decomposition. The CH₄ CI mass spectra of branched alkanes contain [M – H]⁺ ions of lower abundance than those observed for n-alkanes, and fragment ions that identify the site of the branch. The relative abundances, of [M – H]⁺ ions in the CH₄ CI mass spectra are much greater than the abundances of M⁺⁺ ions in the EI spectra and make molecular weight identification or carbon number determination of the compounds much easier.

ICR experiments showed that both CH₄⁺ and C₂H₅⁺ formed [M – H]⁺ and fragment ions although the [M – CH₃]⁺ ions were formed only by dissociative proton transfer from CH₃⁺. There was generally good agreement between the ICR experiments at very low pressures and the high pressure experiments, but a few differences were observed which could be attributed to collisional stabilization of ions in the high pressures of the standard CI experiments.

The CH₄ CI mass spectra of low molecular weight aliphatic esters are relatively similar. The relative abundances of [M + H]⁺ ions in these spectra are larger than the relative abundances of M⁺⁺ ions in their EI mass spectra. [M – H]⁺ ions are also observed. Acyl ions, characteristic of the acid group, are generally formed. If the alkyl group in the ester is C₂ or higher, a rearrangement decomposition to give the protonated acid, RCOOH₂⁺ is observed. Rearrangement decompositions are frequently observed in CI spectra, as well as simple cleavage reactions at the protonated site. In addition to [M + H]⁺ ions, many of the esters give low abundance [M + C₂H₅⁺] and [M + C₃H₅⁺] ions. The presence of three ions at m/z values of X, X + 28, and X + 40 indicates MW = (X – 1). Alkyl fragment ions from the alcohol portion of the ester are generally observed for esters of the larger alcohols. The spectra of the esters are moderately complex but the major fragment ions can be explained in terms of simple decomposition and rearrangement reactions. The spectra appear to result from predominant attack at the carboxyl group.

Studies on the CH₄ CI mass spectra of methyl esters of long chain fatty acids indicate that [M + H]⁺ ions are abundant peaks for the esters of the C₈–C₂₂ acids. The abundances of [M + H]⁺ ions in the CH₄ CI spectra are much greater than the abundances of M⁺⁺ ions in the EI spectra of the corresponding methyl ester. The relative abundance of [M – H]⁺ ions increases continually as the length of the acid chain increases. Increases were observed in the [M – H]⁺/[M + H]⁺ ratios with increasing acid chain length. Similar observations were reported for the H₂ CI spectra of methyl esters of fatty acids. These observations indicate that although attack is predominantly at the polar carboxyl group for the short chain compounds, hydride abstraction from the aliphatic chain becomes competitive when the polarizability of the hydrocarbon portion of the molecule is sufficiently large.

The CH₄ CI mass spectrum of decanol contains no [MH]⁺ ions: H₂O is easily lost from MH⁺ to form C₁₀H₂₁⁺ as the base peak in the spectrum. Lower carbon number alkyl (C₆H₁₃⁺) and alkenyl (C₆H₁₄⁺) ions are also observed. Significant amounts of [M – H]⁺ ions are also observed. The two high mass ions, [M – H]⁺ and R⁺, differ by 16 mass units and allow easy assignment of the molecular weight. Internal hydrogen bonding was indicated in the CH₄ CI mass spectra of long chain α,ω-diols by the presence of relatively abundant [M + H]⁺ ions, even for the C₄₆ diol. The relative abundance of [M – H]⁺ ions increased with increasing carbon number for these diols, and hydride abstraction apparently occurred randomly from the different methylene groups. These observations also indicate that attack occurs at both the polar substituent (the source of the dipole moment in the molecule) and the nonpolar, but polarizable chain.

Methane CI spectra of several classes of compounds are reviewed in Harrison’s monograph on CIMS.
3.2 Effects of Experimental Mass Spectrometry Parameters

The CH₄ CI mass spectra obtained are essentially independent of pressure over a wide range of pressures if the methane reagent gas is sufficiently pure and the introduction system is sufficiently clean. However, small amounts of impurities (frequently water in the inlet lines for the reagent gas or solvents from the sample from a probe) can alter the reactant ions and hence the spectra. It is always advisable to examine the reactant ions during the course of CIMS experiments, particularly with highly reactive ions like CH₅⁺ and C₂H₅⁺ that will react with most polar impurities to form reactant ions that are weaker acids and will cause significantly less fragmentation. Since there are no standard compilations of CI spectra for comparison, differences in abundances of fragment ions caused by different reactant ions in what is supposed to be pure CH₄ will probably not cause significant problems. However, for quantitative studies, a change in reactant ions from CH₅⁺/C₂H₅⁺ to H₃O⁺ or CH₃OH⁺ (from impurities in a sample introduced through a probe) can cause a significant change in the relative abundance of MH⁺ ions and greatly affect the accuracy of the experiment.⁵³

Neither the electron energy nor the electron current has any significant effect on CH₄ CI spectra. This lack of effect is expected since the ions of the analyte are produced by reactions of ions that are themselves produced by ion/molecule reactions in methane. Any excitation energy in the initially formed CH₃⁺ or CH₄⁺ that might be carried over into the C₂H₅⁺ or CH₅⁺ ions would most probably be lost through collisions with methane before reacting with the analyte. Increasing the electron energy generally increases the total ion current and CI sensitivity. The higher energy electrons have a greater penetration depth into the source of the mass spectrometer and consequently increase the concentration of ions in the volume from which the ions most efficiently leave the source. In addition more ions can be produced from 250 eV electrons than from the traditional 70 eV electrons used in EI experiments.

Some (but not all) mass spectrometers (mostly magnetic instruments) have a repeller field in the source to improve the efficiency of the ion extraction. Many of the newer instruments have no added fields in the CI source. The CH₄ CI spectra are essentially independent of repeller field within the source as long as the voltage is of the order of 10 V or less. Very high repeller fields can cause decomposition of the ions within a high-pressure source.⁴³ Using a modified source with grids to maintain an electric field gradient within the source, one can decompose ions within the source to obtain high-pressure collisional activation (or decomposition) of sample ions.⁵⁵

The CH₄ (and other) CI spectra can depend on sample size. If the sample size is sufficiently small, then the only ions that are produced are those from reaction of the reactant ions with the analyte. If the sample size is sufficiently large (not always easy to establish), sample ion/sample molecule reactions will occur and these reactions may alter the spectra significantly. Sample ion/sample molecule reactions will generally not be noticed even if they occur because systematic observations of spectra with changing concentrations are seldom made. Clear evidence of sample ion/sample molecule reactions is shown by the presence in CI mass spectra of protonated dimer ions, MH₂⁺, at large sample concentrations. These ions are often observed from probe samples where it is impossible to control the sample pressure. These ions will generally create no difficulties in structure or molecular weight determination, as long as one recognizes their occurrence. Examination of CI spectra across a chromatographic peak or during heating of a probe sample can show that sample ion/sample molecule reactions are occurring. CH₄ CI spectra of polyethylene glycol (PEG) oligomers and PEG ethers obtained by gas chromatography/chemical ionization mass spectrometry (GC/CIMS) showed that the [M + H]⁺ ions were strongly sample-size dependent and suggested that sample ion/sample molecule reactions might be a common occurrence in CIMS.⁵⁶

CH₄ CI spectra are temperature dependent.²⁹,³⁷ In general, the higher mass ions, [M ± H]⁺ decrease in relative abundance as the temperature is increased. One would expect such a phenomenon since the internal energies of the ions and, therefore, their rates of decomposition increase with increasing temperature. If consecutive decompositions occur, the abundances of the intermediate ions may pass through a maximum as the temperature is increased. The stable lower-mass ions almost always increase in relative abundance as the temperature is increased.

The total ion current and sample ion current in CH₄ CI (and with all reagent gases) will pass through maxima as the pressure is increased.³⁸ The pressure corresponding to the maximum in sensitivity will vary among instruments since it depends on the source geometry and the pumping capacity of the system. The reaction time and the extent of ion/molecule reactions increase with increasing pressure; therefore, the analyte ions will increase in relative abundance with increasing pressure. However, there are losses from ion scattering in the region immediately outside the source as well as in the mass analyzer region that also increase with increasing pressure. The result of these two competing processes is a maximum in sensitivity with increasing pressure. The maximum in the sensitivity does not, however, correspond to conditions for the greatest extent of ion/molecule reactions.
4 OTHER CHEMICAL IONIZATION REAGENT GASES

4.1 Isobutane

As mentioned in section 2.1, one of the major uses of CIMS is the production of simplified spectra of analytes, for qualitative analysis and for quantitative analysis of mixtures. The CH₄ CI mass spectra frequently contain many fragment ions because CH₅⁺ and C₂H₅⁺ are strong Bronsted acids, and proton transfer to the analyte, A, produces excited AH⁺⁺ ions which decompose. Use of lower-energy (more weakly acidic) reactant ions will produce spectra with less fragmentation. A commonly used weakly acidic system is i-C₄H₁₀.

The dominant ion produced by EI of i-C₄H₁₀ is the propyl ion, C₃H₇⁺, at m/z 43. The propyl ions react rapidly with i-C₄H₁₀ to form t-C₄H₉⁺ at m/z 57 (Equations 28 and 29). The t-C₄H₉⁺ ion is a much weaker acid than CH₅⁺ or C₂H₅⁺ because the proton affinity of i-C₄H₈ is significantly higher than the proton affinity of CH₄ or C₂H₄: 802.1 kJ/mol, compared with 543.5 kJ/mol and 680.5 kJ/mol.¹³

\[
i-C₄H₁₀ + e⁻ \rightarrow s-C₃H₇⁺ + CH₃⁻ + 2e⁻ \quad (28)
\]
\[
s-C₃H₇⁺ + i-C₄H₁₀ \rightarrow t-C₄H₉⁺ + C₃H₈ \quad (29)
\]

Because the t-butyl ion is a much weaker protonating agent (Brønsted acid) than CH₅⁺ or C₂H₅⁺, less energy is transferred in proton transfer to form AH⁺⁺ and there is much less fragmentation in i-C₄H₁₀ CI spectra than in CH₄ CI spectra.¹⁰,¹⁰ The i-butyl ion is also a weaker Lewis acid than C₂H₅⁺.¹⁷ Adduct ions, [M + C₂H₅]⁺, are observed in the i-C₄H₁₀ CI spectra of certain compounds.

Most i-C₄H₁₀ CI spectra of complex organic molecules contain abundant [M + H]⁺ ions, often with very little or no fragmentation. Consequently, i-C₄H₁₀ CI has been used to identify compounds in mixtures from sets of likely possibilities. The i-C₄H₁₀ CI spectra of many barbiturates and other commonly used drugs were sufficiently different and easily recognizable that these drugs could be identified in complex mixtures by vaporizing the samples directly into the source of a mass spectrometer (without the time of a chromatographic separation), even from gastric contents in drug overdose cases.⁴¹,⁴² Quantitative analyses of mixtures were also achieved with i-C₄H₁₀ CI by vaporizing the samples directly into the source of the mass spectrometer. Calibration curves and an internal standard were needed.⁴³

Because both fragment ions and MH⁺ ions are observed in reasonable abundances, i-C₄H₁₀ CI has been successfully used as a stereochemical probe for cyclic diols and their derivatives.⁴⁴,⁴⁵ The i-C₄H₁₀ CI spectra of isomers of adamantanediol dimethyl ethers and dihydroxyprotoadamantanes for which internal hydrogen bonding was possible in the protonated molecules, MH⁺, contained MH⁺ ions as the most abundant peak. Internal hydrogen bonding was possible for all three isomers of the 2,4-adamantanediacetales, and the i-C₄H₁₀ CI spectra were virtually indistinguishable; therefore the nature of the derivative is critically important in determining the stereochemistry of ring systems.⁴⁵

The i-C₄H₁₀ CI spectra are sensitive to the pressure of the i-C₄H₁₀ reagent gas and, consequently, the spectra will not be highly reproducible from one instrument to another in the extent of fragmentation because the pressures are seldom measured in most commercial instruments.³⁰,³⁶ If any pressures are reported for CI reagent gases, the values are often the ionization gauge pressure well removed from the ionization source itself. Although the source pressure and ionization gauge pressure are proportional to each other, the ionization gauge pressure does not provide a reproducible measure of source pressure. In general, the extent of fragmentation decreases with increasing pressure of the i-C₄H₁₀ reagent gas.

The pressure dependence of i-C₄H₁₀ CI spectra results partly from the collisional stabilization of the (probably slightly) excited analyte ions, AH⁺⁺, produced by proton transfer from t-C₄H₉⁺. However, the major cause of the pressure dependence of the spectra is the change in the composition of the reactant ions with increasing pressure. The s-propyl ion, C₃H₇⁺, is a stronger Bronsted acid and stronger Lewis acid than t-C₄H₉⁺; consequently, the analyte ions produced by reactions from C₃H₇⁺ will contain more internal energy and dissociate more extensively than analyte ions produced by reactions from t-C₄H₉⁺.

As noted above in Equations (28) and (29), the propyl ions are the major ion in the EI mass spectrum of i-C₄H₁₀, and these propyl ions (m/z 43) react to form t-butyl ions (m/z 57) as the pressure is increased. The ratio, I(57)/I(43) is a sensitive increasing function of i-C₄H₁₀ pressure and can be used as a method of obtaining reproducible, even though not accurately known, pressures. A method has been proposed for the calculation of source pressures under CI conditions from the ionic distributions.⁴⁶ Realistic estimates of pressures in the CI source or the reactant ion spectrum are seldom given with the presentation of CI spectra.

4.2 Ammonia

Another commonly used proton transfer reagent gas system is NH₃. Ammonia is a stronger base than i-C₄H₈ and, consequently, NH₄⁺ should be an even more selective reactant ion than t-C₄H₉⁺.³⁹ The reactant ion spectrum in NH₃ is a complex function of temperature, pressure, and reaction time. The dominant ions under normal CI conditions are NH₄⁺ at m/z 18 and NH₄⁺·NH₃.
at $m/z$ 35 with lesser amounts of the more highly solvated ammonium ions.\textsuperscript{(47,48)} Because the reactant ion distribution is very sensitive to the experimental conditions of temperature and pressure, the NH$_3$ CI spectra are also sensitive to these conditions.

Early work on NH$_3$ CIMS showed the expected selectivity.\textsuperscript{(48–50)} Very basic compounds, such as amines, amides, and $\alpha,\beta$-unsaturated ketones, gave [M + H]$^+$ and their solvated [M + NH$_4^+$] or [M + H + NH$_3^+$] ions. Less basic compounds such as ketones, esters, ethers, anhydrides, and polyhydroxy compounds reacted by adduct formation to give [M + NH$_3^+$] and lesser amounts of [M + NH$_4^+ + NH_3^+$] ions. Alkanes, alkenes, aromatic hydrocarbons, and alcohols gave no sample ions with small sample sizes. Substitution ions were also observed, [M + NH$_4^+ - H_2O$]$^+$ that have the same nominal mass as M$^+$.

The mechanism for the formation of sample ions is complex since several reactions are possible, depending on the PA of the sample (Equations 30–36):

\begin{equation}
\text{NH}_4^+ + \text{A} \rightarrow \text{AH}^+ + \text{NH}_3 \quad (30)
\end{equation}

\begin{equation}
\text{AH}^+ + \text{NH}_3 \leftrightarrow \text{ANH}_4^+ \quad (31)
\end{equation}

\begin{equation}
\text{NH}_4^+ + \text{A} \leftrightarrow \text{ANH}_4^+ \quad (32)
\end{equation}

\begin{equation}
\text{ANH}_4^+ + \text{NH}_3 \leftrightarrow \text{ANH}_4^+ \cdot \text{NH}_3 \quad (33)
\end{equation}

\begin{equation}
\text{NH}_4^+ \cdot \text{NH}_3 + \text{A} \leftrightarrow \text{AH}^+ + 2\text{NH}_3 \quad (34)
\end{equation}

\begin{equation}
\text{NH}_4^+ \cdot \text{NH}_3 + \text{A} \leftrightarrow \text{ANH}_4^+ + \text{NH}_3 \quad (35)
\end{equation}

\begin{equation}
\text{NH}_4^+ + \text{XOH} \rightarrow [\text{X} + \text{NH}_4 - H_2O]^+ \quad (36)
\end{equation}

Equations (30) and (31) represent proton transfer to a basic compound, PA(A) > PA(NH$_3$), followed by solvation, and possibly by additional solvation, Equation (33), at high pressures and low temperatures. This reaction sequence will give ions at masses $X + 1$, $X + 18$ and $X + 35$ in ratios that depend on the pressure of NH$_3$ and the temperature. Equation (32) represents equilibrium (or at least a reversible addition) of NH$_4^+$ with a compound that is less basic than ammonia and cannot accept a proton from direct reaction. This adduct ion can also solvate further by Equation (33). Equations (34) and (35) show the competing reactions of the solvated ammonium ion with the analyte: Equation (34) will occur with very basic compounds and Equation (35) will occur with less basic compounds. Equation (36) is observed with certain hydroxy-containing compounds. Despite these complications, NH$_3$ CI spectra are frequently used and an extensive review is available.\textsuperscript{(48)}

It was reported many years ago that useful spectra could be obtained from CH$_4$/NH$_3$ mixtures containing only small amounts of NH$_3$ (1–3%).\textsuperscript{(51)} In these mixtures, the dominant reactant ion was NH$_4^+$ and there was no NH$_4^+ \cdot NH_3$. Consequently, the reactions were much simpler. By altering the concentrations of NH$_3$ and CH$_4$ in mixture one can obtain spectra with essentially no fragmentation, or spectra with reasonable fragmentation if CH$_3^+$ and C$_2$H$_5^+$ ions are present as reactant ions as well as NH$_4^+$.

With CH$_4$/NH$_3$ mixtures containing a low concentration of NH$_3$, one can observe [M + NH$_4^+$] ions for compounds which cannot be detected using pure NH$_3$ as the reagent gas. It was shown from high pressure and ion cyclotron resonance/mass spectrometry (ICR/MS) experiments that an additional reaction involving the [M + NH$_3^+$] adduct was necessary to remove sample containing ions from the spectrum and therefore reduce the sensitivities of polar, but not very basic compounds.\textsuperscript{(52,53)}

\begin{equation}
[M + NH_4^+]^+ + NH_3 \rightarrow NH_4^+ \cdot NH_3 + M \quad (37)
\end{equation}

In order for the reaction (Equation 37) to be fast, it must be exothermic, and will be observed, therefore, with those compounds that are less basic than ammonia and solvate the ammonium ion less strongly than does NH$_3$, $D(M - NH_4)^+ < D(NH_3 - NH_4^+)$. Experiments have been done using a mixture of CH$_4$ with 5% of a 1/1 $^{15}$NH$_4$/$^{14}$NH$_3$ mixture to aid in identifying the composition of the sample ions, since ions at X and X + 17 can be [M + H]$^+$ and [M + NH$_4^+$] or [M + NH$_3^+$] and [M + NH$_4^+ + NH_3^+$].\textsuperscript{(54)} At the pressures of this mixture used in these experiments, the reactant ion spectrum consisted of essentially equal abundances of $^{14}$NH$_4^+$ and $^{15}$NH$_4^+$ at $m/z$ 18 and 19, with small amounts of the CH$_3^+$ and C$_2$H$_5^+$ ions as well. A sample ion containing NH$_4^+$ appeared as two peaks of approximately the same intensity. The spectrum of hexyl acetate contained a low abundance ion at $m/z$ 145 and two ions of essentially equal intensity at $m/z$ 162 and 163. Obviously, the species are [M + H]$^+$ at $m/z$ 145 from reactions of CH$_3^+$/$C_2H_5^+$ and [M + NH$_4^+$] at $m/z$ 162/163.

One of the first uses of NH$_3$ in CIMS was for the differentiation among primary, secondary, and tertiary amines from a comparison of the spectra obtained with NH$_3$ and with ND$_3$.\textsuperscript{(55)} In these experiments, all of the active hydrogens of the amine are exchanged with the ND$_3$; therefore, there is a distinct mass shift in the spectra depending on the number of labile hydrogens in the molecule. The NH$_3$ CI spectra of 2,6-dimethylaniline and the isomeric N-ethyl aniline each contained two peaks at $m/z$ 122 and 139, [M + H]$^+$ and [M + H + NH$_3^+$]. The ND$_3$ CI spectra of 2,6-dimethylaniline contained two peaks at $m/z$ 125 (CH$_3$)$_2$C$_6$H$_4$ND$_3^+$ and 145, (CH$_3$)$_2$C$_6$H$_4$ND$_3^+$-ND$_3$. However, the ND$_3$ CI spectrum of N-ethyl aniline contained two peaks at $m/z$ 124 and 144 because there was one less exchangeable hydrogen.
in the molecule. The use of labeled CI reagent gases (ND₃, CH3OD, D₂O) to determine the number of active hydrogens in molecules is well established.⁵⁵

4.3 Tetramethylsilane

Many different gases and liquids have been used as CI reagent gases, although methane, isobutane, and ammonia are the most common. Another reagent that has been used is tetramethylsilane, (CH₃)₄Si, the silicon analog of neo-pentane. Although this reagent gas has not been routinely used for analysis, there are some interesting chemical reactions that have been observed with this reagent gas and the trimethylsilyl ion is analogous to the t-buty1 ion. Tetramethylsilane is a liquid, but its vapor pressure is sufficiently high that it can be used with commercial gas introduction systems. It is advisable to keep the liquid tetramethylsilane in a container of water to reduce the pressure variations in the source because of temperature variations in the room.

The dominant ion produced by EI of (CH₃)₄Si is the trimethylsilyl ion, (CH₃)₃Si⁺, the silicon analog of (CH₃)₃C⁺, the t-buty1 ion. Since (CH₃)₃Si=CH₂ is not a stable species, its heat of formation and proton affinity have been determined by ion/molecule reactions rather than conventional thermochemistry.⁵⁹ The ionic chemistry of (CH₃)₄Si is very different from that of i-C₄H₁₀ or of i-C₅H₁₂ and, by inference of (CH₃)₃C.⁵⁷,⁵⁸ The t-buty1 ion does not add to saturated hydrocarbons, but the trimethylsilyl ion does add to tetramethylsilane to form [Si₂(CH₃)₇]⁺ as a major product ion. There are other, less abundant product ions in high pressures of tetramethylsilane, including an ion at m/z 91, (CH₃)₃SiOH₂⁺, formed from reactions with impurities of water in the inlet system. Because (CH₃)₃Si⁺ is both a weak Brønsted and a weak Lewis acid, the major reaction with polar compounds is adduct formation to give [M + (CH₃)₃Si⁺] ions and there are only slow reactions with hydrocarbons.⁵⁹–⁶¹ The ever-present impurity ion, (CH₃)₃SiOH₂⁺ at m/z 91, reacts by proton transfer to give [M + H]⁺ ions or by displacement to give [M + (CH₃)₃Si⁺] ions.

Tetramethylsilane has been used as CI reagent either as a pure substance or diluted with methane, nitrogen, or isobutane. Dilution with methane reduced problems associated with source contamination by the reagent gas, increased the sensitivity for samples, and simplified the reagent ion spectrum by reducing the abundance of (CH₃)₃Si⁺ ions.⁶₀,⁶¹

In experiments derived from the technique used in the mass spectral analysis of biomedical samples (using a mixture of labeled and unlabeled samples), a 1/1 mixture of (CH₃)₄Si with (CD₃)₄Si was used to give equal abundances of [M + (CH₃)₃Si⁺] and [M + (CD₃)₃Si⁺] ions for the compounds. The adduct ions could easily be identified by the two peaks of equal abundance separated by 9 mass units.⁶¹

Tetramethylsilane CIMS can be used to characterize alcohols, since adduct ions are formed. Early ICR experiments showed both [M + (CH₃)₃Si⁺] and (CH₃)₃SiOH₂⁺ ions are products from reactions of (CH₃)₃Si⁺ with ethyl and higher alcohols having β-hydrogens.⁶² The early high-pressure CI experiments showed only adduct ions.⁵⁹ From examination of the tetramethylsilane spectra of alcohols across the chromatographic peaks in GC/CIMS experiments, it was observed that the ratio, I([M + 73]⁺)/I([CH₃)₃SiOH₂⁺]), went through a maximum across each chromatographic peak.⁶³ These observations and ICR experiments showed that the reaction was the two-step sequence (Equations 38a, 38b and 39):

\[
\text{R}^+ + (\text{CH}_3)_3\text{SiOH} \quad (38a) \\
(\text{CH}_3)_3\text{SiOH}^+ + \text{ROH} \quad (38b) \\
(\text{CH}_3)_3\text{SiOH}_2^+ + \text{R}^- \quad (39)
\]

Primary, secondary, and tertiary alcohols could easily be distinguished. The relative sensitivities for the alcohols were essentially independent of molecular weight and temperature (120–260 °C).

Relative molar sensitivities in GC/CIMS using tetramethylsilane as the reagent gas could be described reasonably well from theoretical models for rate constants of ion/molecule reactions.⁶⁴ Significant differences were observed in the temperature dependence of several oxygenated compounds. For compounds for which sample ions were formed by the two-step mechanism, Equations (38) and (39), there was essentially no change in sensitivity with increasing temperature. However, there was a significant decrease in sensitivity with increasing temperature for those compounds for which the [M + (CH₃)₃Si⁺] ions were formed by collisional stabilization of the adduct ion.⁶⁴

The selectivity of (CH₃)₃Si⁺ ions for the identification and quantitative analysis of polar compounds in complex mixtures was demonstrated by an analysis of oxygenated compounds in gasoline.⁶⁵ The oxygenated compounds could be unambiguously identified and quantified from selected ion traces in GC/CIMS experiments. Relative standard deviations for short term replications were ~5%.

The association reactions and ionic chemistry of (CH₃)₃Si⁺ have been reviewed recently.⁶⁶
4.4 Other Reagent Gases

Many other compounds have been used as reagent gases for CIMS studies, although few have been extensively used.\cite{67–70}

5 CHARGE EXCHANGE REAGENTS

5.1 Introduction

In the original work (and the patent) on CIMS, all reactions involved proton or hydride transfer or adduct formation. However, subsequently electron transfer or charge exchange reactions became considered as part of CIMS, (Equation 40):

\[ R^{+} + A \rightarrow A^{+} + R \]  

(40)

Using the fundamental postulate of ion/molecule reactions, that only exothermic reactions will be fast, one can calculate the thermochemistry of this electron or charge transfer reaction from the IPs (energies) of R and A, (Equation 41):

\[ \Delta H^{\circ}(40) = \text{IP}(A) - \text{IP}(R) \]  

(41)

Consequently, if the IP of the analyte, A, is less than the IP of the reactant, R, then the charge exchange reaction will be exothermic and, in all probability, fast.

In addition, the greater the exothermicity of the reaction, the greater the internal energy in the A\(^{+}\)\(+\) ion and the greater the extent of dissociation or fragmentation observed in the charge exchange CI spectrum. Consequently, if one wishes to detect all compounds in a mixture, one will choose a reagent gas that has a high IP (one of the rare gases) and it is likely that there will be abundant fragment ions in the spectra. Conversely, if one wishes selective detection or very little fragmentation, one would choose a reagent gas with a low IP, but with an IP that is larger than the IP of the sample to be analyzed.

There is an added complication that many compounds (including practically all polar compounds) will react with themselves to form other ions (generally protonated species). Consequently, the choice of reagents for charge exchange is more limited than the choice for proton or hydride transfer in high-pressure mass spectrometry. In addition, the distribution of the reagent ions is sensitive to impurities, particularly water. Consequently, care must be taken to keep the gas inlet lines scrupulously dry. It is probably realistic that the \(^{13}\)C isotope ratios will be unreliable because of the formation of MH\(^{+}\) ions from hydrogen-containing ions among the reactant ions.\cite{71}

The mechanisms for the formation of fragment ions in charge exchange CIMS are very different from those in proton or hydride transfer since the decomposing species are very different: A\(^{+}\)\(+\) decomposes after charge exchange and AH\(^{+}\) decomposes after proton transfer. The decomposition mechanisms after charge exchange are essentially the same as those after EI. There is a major difference between charge exchange and EI, however. In charge exchange, the A\(^{+}\)\(+\) ions have a well-defined internal energy: IP(R) − IP(A). In EI, the A\(^{+}\)\(+\) ions have a distribution of energies and decompose at different rates.

Charge exchange reactions are the initial ion/molecule reactions involved in atmospheric pressure ionization (API) or atmospheric pressure chemical ionization (APCI). The N\(_{2}\)\(^{+}\) ions (produced by direct ionization) react rapidly with O\(_{2}\) because IP(N\(_{2}\)) > IP(O\(_{2}\)) and O\(_{2}\)\(^{+}\) ions (formed by direct ionization and charge exchange) react with samples and or impurities in the gas to produce other ions which may be sample ions or which may react with sample ions. O\(_{2}\)\(^{+}\) charge exchange has been shown to be a very sensitive technique for the detection of impurities in air.\cite{72}

5.2 Helium

On the basis of the discussion above, He would be the worst possible charge exchange reagent gas because its IP (24.6 eV) is much greater than the IPs of practically all compounds of interest (\(\sim\)8–10 eV).\cite{73} He is the most common carrier gas in gas chromatography (GC) and is obviously a reagent gas to try, although there have been few experiments using He for the reasons given above.

GC/CIMS experiments using He as the carrier gas were used to detect SF\(_{6}\) at the ppb level in air.\cite{74} The mass spectrum of SF\(_{6}\) obtained under these conditions was surprisingly similar to the EI spectrum. Neither the EI spectrum nor the “He charge exchange” spectrum contained M\(^{+}\) \(+\) ions at m/z 146. Both spectra contained (M – F)\(^{+}\) as the base peak. The “He charge exchange” spectrum contained 108 as 11% of the base peak and 89 at 68% of the base peak. The EI spectrum shows 108 at 9–11% of the base peak and 89 as 20–26% of the base peak.\cite{75} Although this spectrum shows somewhat more fragmentation, the extent of fragmentation is not nearly as large as one would expect for the amount of internal energy in a simple molecule: (24.6–15.3) eV.\cite{73}

It is likely that processes other than charge exchange by He\(^{+}\) produce the spectrum, or at least make significant contributions to it. Some collisional stabilization of the highly excited SF\(_{6}\)\(^{+}\) occurs that will reduce the extent of fragmentation. In addition, the initial high-energy electrons lose energy in collisions and produce more electrons that may be able to ionize the sample molecules. Since the ionization cross-section of He is much smaller than ionization cross-sections of other molecules, direct
EI may well be occurring. Experiments in our laboratory showed spectra of compounds from “He charge exchange” that contained more fragmentation than the EI spectra, but which were sufficiently like the EI spectra to be recognizable. Consequently, “He charge exchange” CIMS may be useful.

5.3 Benzene, Chlorobenzene

The more common use of charge exchange reagents is for selective detection of certain classes of compounds and not others. One obvious difference among classes of compounds is the difference in IPs between saturated and unsaturated compounds. The IPs of unsaturated compounds are consistently lower than the IPs of similar saturated compounds. Chlorobenzene, (C₆H₅Cl, IP = 9.04 eV) was found to be a selective reagent gas for the detection of aromatic hydrocarbons in the presence of alkanes and cycloalkanes. The C₆H₅Cl⁺⁺ ion is the dominant species among the reactant ions at “high” pressures (~0.04 torr) and essentially the only sample ions observed for chlorobenzene CIMS of alkylbenzenes and alkynaphthalenes are the molecular ions. In these experiments there was an apparent decrease in the relative sensitivities of the aromatic hydrocarbons with increasing molecular weight that was attributed to the electron multiplier. To a first approximation, the sensitivities of the aromatic hydrocarbons were essentially independent of molecular weight. Complex mixtures of gasoline or fuel oils could be quantitatively analyzed using chlorobenzene CI without chromatographic separation.

Benzene (C₆H₆, IP = 9.25 eV) has also been used for selective detection in GC/CIMS studies. By recording the ion current of the C₆H₅Cl⁺⁺ during a GC/CIMS experiment (Reactant Ion Monitoring), one could see that C₆H₅Cl⁺⁺ ions reacted with unsaturated compounds in mixtures but not with saturated compounds. Again, benzene CI mass spectra contain essentially no fragment ions. Quantitative studies using benzene GC/CIMS showed that the relative molar sensitivities of a series of alkylbenzenes (C₆–C₁₂) and olefins (C₃–C₅) were essentially constant and the relative molar sensitivities of alkanes (C₂–C₁₂) were less than 1% of these values. Calculations of rate constants (molar sensitivities) from theories of ion/molecule reaction rate constants predict only a small variation in the relative rate constants for charge exchange of C₆H₆⁺⁺ with alkylbenzenes of increasing molecular weight. Similar conclusions would be noted for charge exchange from C₆H₅Cl⁺⁺.

Benzene or chlorobenzene charge exchange has an advantage over low-voltage EI, the commonly used technique for mass spectrometric analyses of aliphatic/aromatic hydrocarbon mixtures. The relative molar sensitivities of substituted alkylbenzenes are independent of structure for benzene CIMS and very strongly dependent on structure for low-voltage EIMS. Benzene or chlorobenzene charge exchange CIMS may be more sensitive than low-voltage EIMS, but definitive experiments have not been performed.

5.4 Nitric Oxide

Although the ion/molecule reactions with NO as a CI reagent gas are moderately complex, nitric oxide has been used extensively as a CI reagent gas. The major ionic reactions which can occur with NO⁺ are the following (Equations 42–44):

\[
\text{NO}^+ + M \rightarrow M^{**} + \text{NO}^* \quad (42)
\]

\[
\text{NO}^+ + M \rightarrow [M + \text{NO}]^+ \quad (43)
\]

\[
\text{NO}^+ + M \rightarrow [M - H]^+ + \text{HNO} \quad (44)
\]

In addition X⁻ abstraction (X = HO, Cl) reactions have been observed. Esters and ketones give [M + NO]⁺ ions, as long as IP(M) > IP(NO); aldehydes can be differentiated from ketones because aldehydes give abundant [M – H]⁺ ions rather than [M + NO]⁺ adduct ions; alkanes give essentially only [M – H]⁺ ions. The [M + NO]⁺/[M⁺] ratio for a series of substituted benzenes gave a good correlation with the Hammett substituent constant, σ_p⁺. Analysis of the data for many substituted benzenes showed that NO⁺ has an “effective IP” of ~8.7 eV for charge exchange reactions, rather than the observed value of 9.3 eV.

The mass spectrometric analysis of alcohols has traditionally been difficult. EI, CH₄ CI, and i-C₄H₁₀ CI have been used with some success and tetramethylsilane CI can also differentiate among primary, secondary, and tertiary structures. The CI techniques are improvements over the EI technique since some sample ions containing the correct number of C-atoms are observed as noted in sections 3.1 and 4.1. The NO CI spectra of primary, secondary, and tertiary alcohols were relatively easily distinguishable. Primary alcohols generally gave NO CI spectra which contained [M + NO]⁺, [M – H]⁺, and some [M – 3]⁺ ions; secondary alcohols gave NO CI spectra which contained abundant [M – H]⁺ and [M – OH]⁺ ions; and tertiary alcohols gave predominantly [M – OH]⁺ ions. The [M – 3]⁺, and [M – 2 + NO]⁺ ions were attributed to oxidation of ions by NO, since the abundance of these ions vanished with the use of dilute mixtures of NO in N₂. Alkanes also gave ions from ionic reactions of sample ions with the reagent gas, NO.

The presence of the [M – 3]⁺ and [M – 2 + NO]⁺ ions and other unexpected ions show one of the difficulties of working with NO as a reagent gas: oxidation of ions.
addition, NO also rapidly oxidized the hot wire filament used to generate electrons for ionization of the reagent gas. One solution to the problem of rapid oxidation of the filament that produces the ionizing electrons was to use a discharge source that does not have a filament.\(^{84}\) Although the NO CI spectra of hydrocarbons are not single-species spectra, the extent of fragmentation is relatively small so that there is little overlap in the masses of spectra of the different classes of compounds of approximately the same molecular weight. Complex mixtures of hydrocarbons (C\(_6\)–C\(_{20}\)) were analyzed using GC/CIMS with NO as the reactant gas. Complete chromatographic separation was not obtained because of the complexity of the mixtures, but type analyses by carbon number were obtained from the NO CI mass spectra.\(^{85}\)

Another way to increase the lifetime of the filament and also to reduce the oxidation reactions by NO is to use dilute mixtures of NO in other reagent gases – N\(_2\) and H\(_2\) were successfully used.\(^{86,87}\) The exact composition of the mixtures was determined by the source pressures which were used, but these reagent mixtures allowed the reactions of NO\(^+\) to be observed without the oxidation processes.

Another solution to the oxidation problems with pure NO was to use N\(_2\)O as the reagent gas.\(^{88}\) Nitrous oxide does not oxidize the hot filaments rapidly. The high-pressure mass spectrum of N\(_2\)O contains about 33% NO\(^+\) ions and 63% N\(_2\)O\(^+\) ions, independent of the pressure of nitrous oxide. The N\(_2\)O\(^+\) ions react predominantly by dissociative charge exchange (IP(N\(_2\)O) = 12.9 eV) to give characteristic fragment ions and the NO\(^+\) ions undergo the reactions described above. No oxidation products like \([M-3]^+\) ions were observed; but the extent of fragmentation was much higher using this reagent gas than using pure NO.

6 NEGATIVE ION CHEMICAL IONIZATION

6.1 Introduction

Negative ions were observed in the very early gaseous discharge experiments (H\(^-\), O\(^-\), Cl\(^-\), C\(^-\), C\(_2\)^\(-\)) in abundances that were sometimes comparable to the positive ions.\(^{13}\) However extensive work and analytical applications of negative ion mass spectrometry are relatively recent. Historically, the mass spectrometers (both research and commercial analytical) were designed for the detection of positive ions. At the very low pressures of most mass spectrometric experiments, the efficiency for the production of positive ions is some 100–1000 times as large as the efficiency for production of negative ions.\(^{89}\) Electron capture of 70 eV electrons is very inefficient. In addition, the negative ion spectra that were obtained contained predominantly low-mass ions that were not helpful in identification of compounds.

The dominant reactions for production of negative ions from collisions with electrons are given in Equations (45–47):

\[
\text{AB} + \text{e}^- \rightarrow \text{AB}^- \tag{45}
\]

\[
\text{AB} + \text{e}^- \rightarrow \text{B}^- + \text{A} \tag{46}
\]

\[
\text{AB} + \text{e}^- \rightarrow \text{B}^- + \text{A}^+ + \text{e}^- \tag{47}
\]

Equation (45) is electron capture and is efficient only if AB has a high electron affinity (EA) and if the kinetic energy of the electrons is very low, approximately thermal energy. Equation (46), dissociative electron capture, occurs with electrons with kinetic energies of a few electron volts and will produce negative ions for atoms or small groups with large EA. Equation (47), pair production, occurs with high-energy electrons (greater than the IPs of the molecules) and again produces negative ions of atoms or small groups with high electron affinities.

Negative CIMS should probably be divided into two general categories, one in which the negative ions of the samples are produced by ion/molecule reactions and the other in which the negative ions of the samples are produced by collisionally stabilized electron capture. The mechanisms for the formation of the negative ions are different for the two processes, but both processes may occur under the same conditions and such a distinction is not always made.

6.2 Negative Ion/Molecule Reactions

The rate constants for ion/molecule reactions of many negative ions are essentially the same as the rate constants for positive ions, \(\sim 10^{-9} \text{cm}^3\text{mol}^{-1}\text{s}^{-1}\), as long as the reactions are slightly exothermic.\(^{11}\) The reactions of the negative reactant ions should, therefore, be analogous to the reactions of positive reactant ions in CIMS. The reactions of the negative ions are frequently as in Equations (48–50):

\[
\text{R}^- + \text{SH} \rightarrow \text{S}^- + \text{RH} \tag{48}
\]

\[
\text{R}^- + \text{SH} \rightarrow \text{SH}^- + \text{R} \tag{49}
\]

\[
\text{R}^- + \text{SH} \rightarrow \text{S}^- + \text{RH} \tag{50}
\]

The thermochemistry of Equation (48) is determined by the relative base strengths of R\(^-\) and S\(^-\). If R\(^-\) is a weaker base than S\(^-\), the reaction is exothermic and likely to be fast. Comparisons can be made of the gas-phase acidities of the anions from a standard compilation to predict whether or not a particular reaction will occur.\(^{90}\)
thermochemistry of Equation (49) is determined by the difference in EAs of R and SH. If EA(SH) > EA(R), the reaction will be exothermic and fast. Adduct formation, Equation (50), is likely only if Equations (48) and (49) are both exothermic and the species is polar.

A frequently used negatively charged CI reactant ion is HO\(^-\). It is necessary to produce HO\(^-\) ions by indirect means, and mixtures of \(\text{N}_2\text{O}\) with \(\text{H}_2\), \(\text{CH}_4\), or alkanes have been successful for generating ionic distributions that contain mostly HO\(^-\).\(^{91,92}\) The compositions of the mixtures depend on the pressures, but conditions can be achieved so that the reactant ion spectrum contains predominantly HO\(^-\) ions. The process for producing the HO\(^-\) ions (Equations 51 and 52) involves the formation of \(\text{O}^+\) from \(\text{N}_2\text{O}\) by low energy electrons produced from the high pressures of the reagent gas and subsequent abstraction of \(\text{H}^+\) by \(\text{O}^+\).

\[\text{e}^- + \text{N}_2\text{O} \rightarrow \text{O}^+ + \text{N}_2 \] (51)

\[\text{O}^+ + \text{XH} \rightarrow \text{HO}^- + \text{X}^+ \] (52)

The dominant reaction of HO\(^-\) with acids, esters, ketones, alcohols, thiols, alkenes, alkanes, alkylbenzenes, and alkynaphthalenes is proton transfer to give primarily \([\text{M} - \text{H}]^-\) ions. Some fragment ions are produced and some oxidation products, \([\text{M} - 3]^-\), are observed, but the spectra of many compounds are simple. Since proton transfer from alkanes and cycloalkanes to HO\(^-\) is not observed, it was possible to analyze complex petroleum mixtures for aromatic compounds without separation from the alkanes and cycloalkanes.\(^{92}\) There appeared to be a variation of a factor of 2–3 among the relative sensitivities of alkyl aromatic hydrocarbons. At high pressures, there are additional ions in the spectra of alkylbenzenes and olefins that result from reactions of the \([\text{M} - \text{H}]^-\) ions with \(\text{N}_2\text{O}\).\(^{91}\)

The HO\(^-\) CI spectra of a series of steroids and cholesteryl esters proved useful for identification.\(^{93}\) There were abundant \([\text{M} - \text{H}]^-\) ions in these spectra which allowed easy determination of the molecular weights. The acid anion is a major fragment ion from nucleophilic displacement, (Equation 53):

\[\text{HO}^- + \text{RCOO}' \rightarrow \text{RCOO}^- + \text{HOR}' \] (53)

This reaction is not the same as the nucleophilic reaction in solution that cleaves the acyl oxygen bond to give RO\(^-\).

The HO\(^-\) CI spectra of the cholesteryl esters may be compared with the \(i\)-\(\text{C}_4\text{H}_{10}\) CI (\(t\)-\(\text{C}_4\text{H}_{9}^+\)) spectra discussed earlier.\(^{7}\) The significant abundance of \([\text{M} - \text{H}]^-\) ions from reactions with HO\(^-\) and the absence of \([\text{M} + \text{H}]^+\) ions from reactions with \(t\)-\(\text{C}_4\text{H}_{9}^+\) suggest that proton abstraction from the sample in negative ion CI imparts less energy to the sample ions than proton transfer to the sample in positive ion CI. The CI spectra of a series of terpene alcohols gave mostly \([\text{M} - \text{OH}]^+\) ions from reactions with \(i\)-\(\text{C}_4\text{H}_{10}\) and predominantly \([\text{M} - \text{H}]^-\) ions from reactions with HO\(^-\).\(^{94}\) However, in this case it is likely that the \([\text{M} - \text{OH}]^+\) ions are formed by HO\(^-\) abstraction by \(t\)-\(\text{C}_4\text{H}_{9}^+\), rather than dissociative proton transfer. The \(i\)-\(\text{C}_4\text{H}_{10}\) CI spectra of a series of terpene esters contained mostly alkyl ions and essentially no \([\text{M} + \text{H}]^+\) ions while the HO\(^-\) spectra contained significant amounts of \([\text{M} - \text{H}]^-\) ions, although extensive displacement to give RCOO\(^-\) ions was observed. The HO\(^-\) spectra of methyl esters of long chain fatty acids contain predominantly \([\text{M} - \text{H}]^-\) ions with smaller amounts of RCOO\(^-\) and \([\text{M} - \text{H} - \text{CH}_3\text{OH}]^-\) fragment ions.\(^{95}\) The \(i\)-\(\text{C}_6\text{H}_{10}\) CI spectra of methyl esters of long chain fatty acids contain \([\text{M} + \text{H}]^+\) as the base peak with increasing amounts of \([\text{M} - \text{H}]^-\) ions as the chain length increases.\(^{30}\) Neither reactant ion has a clear cut advantage over the other.

In quadrupole (but not magnetic) mass spectrometers, ions of identical \(m/z\) but opposite charge pass through the quadrupole field and exit at the same point. Consequently, by rapidly alternating the potential on the source of the quadrupole and having one detector for positive ions and another for negative ions, one can detect both positive and negative ions essentially simultaneously under CI conditions.\(^{96}\) Any CI reagent can be used. \(\text{O}_2\) would give charge exchange in both positive and negative ion modes from reactions of \(\text{O}_2^+\) or \(\text{O}_2^-\). \(\text{O}^+\) will react primarily by proton abstraction from the samples. There are no stable negative ions in \(\text{CH}_4\) or \(\text{NH}_3\); therefore, the negative ions formed in these experiments would be formed by electron capture.

6.3 Electron Capture

Among the earliest experiments in negative ion CIMS were those done with \(\text{CH}_4\) as the CI reagent as for the analysis of chlorinated hydrocarbons.\(^{97}\) Since there are no stable negative ions in any reasonable concentrations in high pressures of methane after EI, any sample ions should be produced by capture of thermal electrons. In these experiments there were molecular ion clusters, abundant low molecular weight halogen-containing ions (Cl\(^-\), C\(_2\)Cl\(_2\), H\(_2\)OCl\(^-\), H\(_2\)Cl\(_2\)) and abundant adduct ions at \([\text{M} + \text{Cl}]^-\) and other masses. The spectra were useful, although complex, and were interpreted in terms of electron capture to give some M\(^+\) ions and abundant Cl\(^-\) (and other fragment) ions that reacted with the samples to give the adduct ions (sample ion/sample molecule reactions, as discussed earlier). Subsequent experiments showed that with small sample sizes (obtained by GC/CIMS) of chlorinated...
hydrocarbons and their derivatives, electron capture and dissociative electron capture were the dominant processes and that the adduct ions were formed when larger sample concentrations were present, as would be the case for probe introduction of samples.\textsuperscript{(98)}

This technique of producing low-energy electrons by collisions with methane as the reagent gas is sometimes called “methane enhanced” negative CI.\textsuperscript{(98)} The spectra are sensitive to trace amounts of O\textsubscript{2} and small amounts of oxygen were sometimes added to obtain reproducible spectra. The addition of oxygen to methane can form HO\textsuperscript{−} and other negatively charged ions; so the mixtures will give both electron capture and negative ion molecule reactions.\textsuperscript{(99)} The methane negative ion CIMS of several halogenated benzenes gave predominantly the halogen ions from dissociative electron capture. Use of the CH\textsubscript{4}/O\textsubscript{2} mixture gave spectra with greater abundances of higher molecular weight ions: [M − H]\textsuperscript{−} or [M + O − Cl]\textsuperscript{−} or [M + O − Br]\textsuperscript{−} ions.

The main advantage of electron capture negative ion CIMS is the greatly enhanced sensitivity for compounds with high electron affinities.\textsuperscript{(96)} Using CH\textsubscript{4} as the reagent gas to provide thermal electrons for electron capture and no negative ions for ion/molecule reactions, major differences in sensitivities were observed for negative ions over positive ions: factors of 100 to 1000 for compounds like 9,10-anthraquinone and phthalic anhydride or pentafluorobenzonitrile or 2,4,6-trinitrotoluene. Extremely high sensitivities and low detection limits could be obtained using electron capture negative CI with highly electronegative derivatives or thermal detachment of the

7 ATMOSPHERIC PRESSURE IONIZATION

API or APCI was developed in the early 1970s by Horning et al. at the time that they were evaluating the precision and accuracy of mass measurement of plasma chromatography.\textsuperscript{(105−107)} The source of ionizing radiation was \textsuperscript{60}Ni on gold foil in the ionization chamber (a \textbeta-emitter that was the radiation source used in plasma chromatography). A 25 µm pinhole separated the source at atmospheric pressure from the quadrupole analyzer at \textapprox 10\textsuperscript{−5} torr. Both positive and negative ions could be detected with the system. High purity N\textsubscript{2} (exact value not specified) was additionally purified with a 13X molecular sieve column to remove water and organic impurities.

Because the reactions are occurring at atmospheric pressure (many more collisions of ions with molecules than in a standard CI source) there were problems associated with adsorbed impurities in the inlet lines, in the source, and from previous samples. However, baking the ionization region and working with carefully purified materials reduced these difficulties.

The ionic reactions in an API (APCI) source can be quite complex, depending on the purity of the reagent gas. For extremely high purity N\textsubscript{2}, the reactions are the following (Equations 54 and 55):

\begin{equation}
\text{N}_2^{++} + \text{N}_2 + \text{N}_2 \rightarrow \text{N}_4^{++} + \text{N}_2 \quad (54)
\end{equation}

\begin{equation}
\text{N}_4^{++} + \text{S} \rightarrow \text{S}^{++} + 2\text{N}_2 \quad (55)
\end{equation}
Consequently, one might expect to observe molecular ions and fragments from charge exchange reactions. Somewhat more realistically, it is impossible to remove all of the water from the system; so the following reaction are likely (Equations 56–58):

\[
\begin{align*}
N_4^{++} + H_2O & \rightarrow H_2O^{++} + 2N_2 \\
H_2O^{++} + H_2O & \rightarrow H_2O^+ + HO^* \\
H_3O^+ + nH_2O + N_2 & \rightarrow H_3O^+(H_2O)_n + N_2
\end{align*}
\]

The degree of solvation of H$_3$O$^+$ depends on the concentration of water in the nitrogen reagent gas. Consequently, one might expect to observe MH$^+$ ions with basic compounds and little or no ionization with nonpolar species. If the samples are introduced in a solvent, then N$_4^{++}$ will react with the solvent to form ions that will then react with the sample that is necessarily present at a much lower concentration than the solvent. API mass spectra are strongly dependent on the concentrations of all compounds in the ionization source.

The observations that attracted the greatest attention were the extreme sensitivity of the method for basic compounds and the virtual absence of response for nonpolar species. If the samples are introduced in a solvent, then N$_4^{++}$ will react with the solvent to form ions that will then react with the sample that is necessarily present at a much lower concentration than the solvent. API mass spectra are strongly dependent on the concentrations of all compounds in the ionization source.

The observations that attracted the greatest attention were the extreme sensitivity of the method for basic compounds and the virtual absence of response for nonpolar species. A strong correlation has been established between API sensitivities and the PA or gas-phase basicities of samples: an increase in sensitivity with increasing proton affinity to a limiting value for compounds with PA larger than a certain value (that would depend on the strength of the protonating agent).$^{108}$ With a substantial amount of water in the reagent gas, it was observed that the sensitivities of compounds showed a similar correlation with aqueous basicities.$^{108}$

It was immediately obvious that combinations of API with GC and liquid chromatography would be both useful and relatively straightforward instrumentally. Such combinations are commercially available and routinely used for many analyses.$^{109–111}$

Collisionally induced decomposition (CID), or mass spectrometry/mass spectrometry (MS/MS), has been used extensively with CIMS for identifying, characterizing, or quantifying targeted compounds by decomposing the MH$^+$ or M$^{++}$ ions of each species that are produced from low energy CI reactant ions.$^8$ Similarly, MS/MS has been combined with API or APCl to individual components, generally separated by liquid chromatography or GC.$^{110}$ The analysis of unresolved mixtures can be done with API as was done with CI.

Exchange reactions of ions with labeled polar compounds (such as D$_2$O, ND$_3$, CH$_3$OD) have been used to identify the number of labile hydrogens in molecules.$^{111}$ Such studies can be done in API experiments. If polar solvents are used in liquid chromatography, the sample ions are often solvated with solvent molecules and a small potential and a drying gas are used in the intermediate pressure region to desolvate the sample ions by ion/molecule collisions. Introducing a labeled gas into this region allows the exchange of labile protons to be observed.$^{112}$ Again, continuing the combination of techniques, one can apply MS/MS to these exchanged ions to interpret the CID processes.

### 8 PROSPECTS

CIMS is a “mature” technique: one that is well established and frequently used as an incidental technique in analytical problem solving. Although the basic phenomena are well understood, not all of the details of the reactions or physical processes (ion/electron recombination, ion/ion recombination, radical reactions, surface processes) are understood or easily explained. Additional work on the fundamentals of ion/molecule reactions is needed to explain the analytical observations more completely. Ion/molecule reactions are involved in sample ion production from other mass spectrometric techniques, including fast atom bombardment (FAB), electrospray ionization (ESI), and matrix-assisted laser desorption ionization (MALDI). The extent of involvement of ion/molecule reactions in these techniques is not well understood or always recognized.

CIMS is an analytical application of ion/molecule reactions. As the instrumentation for the study of ion/molecule reactions continues to improve, the potential for the analytical applications of the ion/molecule reactions becomes greater. FTICR and ion trap mass spectrometers have become more available and more easily used for the study of ion/molecule reactions. With these instruments, it is possible to study reactions of carefully chosen reactant ions with samples for selective detection of certain molecular properties (IP, EA, PA, stereochemistry) as well as reactions of sample ions with different neutral compounds. These ion/molecule reactions can be used for characterization of increasingly complex or heavier molecules or to detect more subtle differences in structures of complex molecules.$^{109,113}$ A few measurements of rate constants for H/D exchange have been observed for peptides and proteins, which were interpreted in terms of the structures of the peptides. Reactions of multi-functional ions with samples or reactions of sample ions with multi-functional compounds may be useful for the determination of the stereochemistry of isomeric species.

The drift velocities or mobilities of ions in gases have been measured for many years and the mobilities used to determine the interaction potentials between
these ions and the gases.\textsuperscript{(2,114)} These measurements were initially limited to small ions, but subsequently a technique called “plasma chromatography” was developed for larger molecules as an analytical technique.\textsuperscript{(114)} The mobility of an ion depends on both its mass and its size or shape and the variation with shape or molecular type hindered the acceptance of plasma chromatography for the analysis of small molecules, although the technique is extremely sensitive.

There has been a resurgence of interest in, and improved instrumentation for, ion mobility measurements and the technique is now called “ion mobility spectrometry”.\textsuperscript{(115)} Small differences in reduced mobilities of small molecules (mobilities recalculated to standard conditions) have been interpreted as resulting from different shapes (or sizes) of the ions and demonstrate the potential of ion mobility spectrometry for differentiation of isomers. Quantitative analyses have been demonstrated and the instruments are relatively portable for fieldwork.

The term “ion chromatography” is also used to describe the use of ion mobility measurements for determination of properties of ions. The groups doing “ion chromatography” experiments work on different systems and apply a more theoretical approach to the use of the reduced mobility measurements than those doing ion mobility spectrometry, but the techniques are very similar (if not identical). Recent work in ion chromatography has been directed toward the determination of the conformations of gas-phase ions of macromolecules from comparisons of experimental reduced mobilities with mobilities calculated from potential functions and assumed ionic geometries.\textsuperscript{(116,117)}

1 Introduction

Standard electron capture negative ion mass spectrometry (ECNIMS) has long been known as a sensitive and selective method for the analysis of molecules with positive electron affinities. Applications of this technique for the analysis of environmental contaminants, particularly of halogenated compounds such as polychlorobiphenyls (PCBs), are common. However, the requirement for a moderating gas in the ion source to lower the energy of the electrons into the range required for resonance electron capture generates new experimental variables that are difficult to control. Differences in the moderating gas pressure cause changes in the electron energy distribution and in the resulting ion abundances, whereas small fluctuations in temperature often cause major differences in ion abundance ratios. Even more serious are the uncontrollable reactions between ions, molecules, and radicals within the high-pressure ion source region that give unpredictable spurious product ions, making spectral interpretation difficult and leading to wide variations of negative ion spectra from different instruments. Because of these difficulties, the advantages in sensitivity and specificity of ECNIMS for analysis of electronegative compounds often have been unrealized.

Better results can be obtained by having direct control over the electron energies. Control over electron energies can be achieved using a trochoidal electron monochromator, which allows the operator to tune to or scan a range of electron energies necessary for resonance electron capture. With this device some of the inherent difficulties encountered with ECNIMS can be avoided and reliable spectra for a broader range of compounds becomes possible. The ability to tune to a desired electron energy or to scan over a range of electron energies makes another dimension of analytical information available for identifying compounds. Quadrupole and sector instruments have been equipped with electron monochromators and the results are very promising. A clear advantage of these units is the reproducibility of the data they produce, the potential for three-dimensional spectra for easier interpretation of the results, and the availability of a new dimension of analytical information. These instruments have not shown the sensitivity inherent in the ECNIMS method. Improvements of about two or three orders of magnitude in sensitivity will be required before these instruments can compete with existing technology for trace analysis of environmental residues or other electron-capturing compounds. An improvement in the sensitivity of this magnitude is well within reasonable expectations and it should not be long before gas chromatography/electron monochromator mass spectrometry (GC/EMMS) becomes a standard technique for detecting environmental compounds, explosives and substances of abuse.

1 INTRODUCTION

ECNIMS is one of the most sensitive and specific analytical methods available when applied to the right kind of samples. Compounds that respond well to this technique are those that capture low-energy electrons and form molecular radical anions or dissociative products consisting of radicals and anions. These compounds readily undergo resonance capture of slow electrons because of the presence of electronegative groups or atoms and/or extended conjugated \( \pi \)-systems. Aromatic nitro, carbonyl, phosphate, and halogenated compounds are among the strongest electron absorbers, and for this reason the ECNIMS technique has been favored whenever possible for the analysis of environmental compounds where sensitivity and specificity are of paramount importance.

Although the advantages of ECNIMS are well established, there are equally well-known disadvantages to the
method, including a lack of reproducible data particularly for quantitative studies and the general lack of information on mechanisms of ion formation. Efforts to remedy the problems of reproducibility have met with mixed success, largely because of the difficulty of working with low-energy electrons and the presence of a reagent gas in the ion source that not only generates slow electrons but also adds positive ions to the ion plasma that can react to form spurious ion–ion or ion–molecule reaction products. The potential to solve this problem is embodied in the electron monochromator, which can deliver discrete low-energy electrons in the absence of reagent gases. The electron monochromator has been available for several decades and the use of these devices in the ion source of mass spectrometers was demonstrated almost from the outset. Many of the reproducibility problems associated with ECNIMS can be avoided by using electron monochromator mass spectrometry (EMMS). The specificity of compound detection is enhanced further through the additional dimension of analytical information gained from resonance capture of electrons of discrete energy. ENMS instruments are now commercially available from JEOL USA, Inc and provide an alternative to the standard gas moderated ECNIMS ionization sources. Direct formation of negative ions provides information that can be used to identify target compounds and distinguish isomers. Because there is no reagent gas and no bipolar plasma, the electron monochromator provides highly reproducible negative ion mass spectra and avoids artifacts that can be observed in conventional ECNIMS.

Meanwhile GC/EMMS, when used in conjunction with high-level ab initio computational methods, can provide information on the mechanism of negative ion formation that is difficult to obtain by other methods. Much of the information available on energies of resonance states comes from studies carried out by electron transmission spectroscopy (ETS). This is a powerful technique for studying electronic and vibrational energy levels of electron-absorbing molecules, even for molecules that fail to form stable anions. But the technique gives no information on the nature of the anions being measured. The advantage of EMMS is that the masses of the ions formed are recorded along with the electron attachment energies. Thus, ETS measurements and the data from EMMS are complementary. In this account, emphasis is placed on what can be learned about the mechanistic aspects of resonance electron capture ion-forming reactions in the gas phase using EMMS.

2 BACKGROUND

The production of analytically useful negative ions in mass spectrometry has a history as long as that for chemical ionization mass spectrometry. The terminology “negative chemical ionization mass spectrometry” (NCIMS) or “electron capture negative chemical ionization mass spectrometry” (ECNCIMS) reveals the origin of the method but the terminology itself is somewhat misleading with respect to the process involved in forming negative ions. ECNIMS is a preferred title for this technique because it is free of any suggestions of how the slow electrons necessary for resonance electron capture processes are produced.

Standard ECNIMS has long been known as a sensitive and selective method for the analysis of electronegative compounds, and excellent texts and reviews have been written about the subject. It is the preferred technique, for example, in the analysis of PCBs and other halogenated compounds. Because of the inherent sensitivity of the method, an important application of ECNIMS has been the analysis of tissue and biological fluid samples. Polychlorophenols and biphenyls in human adipose tissues, a variety of chlorinated compounds in human seminal fluids, polychlorinated dibenzofurans, dibenzofloxins and styrenes in fish, and pentachlorophenol and related chlorinated compounds in human organs are just a few examples of analyses that have been carried out by ECNIMS.

To generate the slow electrons required for resonance electron capture, a reagent gas, variously called moderating gas or buffer gas, must be introduced into the ion source. The reagent gas, usually methane or isobutane, acts to remove kinetic energy from the accelerated electrons that are emitted from the filament. A combination of ionization of the reagent gas molecules (Equation 1) that reduces the electron energies to around 30 eV, plus kinematic processes resulting from inelastic collisions with reagent gas molecules, further reduces the electron energies to thermal or epithermal levels. The pressure of the buffer gas, which is usually in the range 53.3–106.6 Pa (0.4–0.8 Torr), determines the final electron energies and their distributions. Typically, the source is operated so that about 50% of the electrons have energies close to 0 eV.

$$2\text{CH}_4 + 2e^- \rightarrow \text{CH}_4^{+\ast} + \text{CH}_3^+ + \text{H}^+ + 2e^- (1\text{eV}) + 2e^- (2\text{eV})$$ (1)

The presence of the reagent gas in the ion source, however, introduces a number of complications so that good control over the ionization process is difficult to achieve. Different gas pressures cause changes in the electron energies and in the resulting relative ion intensities, and small fluctuations in temperature cause major differences in ion abundance ratios. Variations in ion transmission efficiencies of the extraction optics of
different instruments also affect ion abundance ratios.\(^{(22)}\)
Various ions and neutral molecules in the source can react to give unpredictable spurious product ions,\(^{(23–25)}\)
making it difficult to interpret the spectra. Wide variations in electron energies between different instruments may be a factor responsible for the poor reproducibility of negative ion spectra from different laboratories.\(^{(26)}\)
Because of these difficulties, the advantages in sensitivity and specificity for the analysis of electron-negative compounds often are compromised or lost entirely\(^{(22)}\) and the method is often avoided, especially for any kind of semi-quantitative purposes. Nevertheless, ECNIMS would be a powerful tool if the electron energies could be controlled and the ion–ion and molecule–ion interactions avoided. EMMS provides control over the electron energies and also avoids the reagent gas that causes spurious product ions. Most importantly, the use of EMMS provides a new dimension of analytical information to characterize compound classes, which cannot be readily achieved by standard ECNIMS methods.

### 3 ELECTRON–MOLECULE INTERACTIONS

The salient treatises on negative ion resonances (NIR) can be found in the two comprehensive volumes by Christophorou.\(^{(27,26)}\) Excellent reviews on the subject have also been published.\(^{(7,29–31)}\) Only the basics of electron–molecule interactions are mentioned here.

There are three processes leading to the formation of gas-phase negative ions that can be observed by mass spectrometry, and they result from the interaction of neutral molecules with electrons. Ion pair formation occurs when electrons, of energies equal to at least the ionization potential plus electron affinity of the neutral fragment, i.e. electrons of energies \(10–15\ eV\), interact with neutral molecules to give excited states that dissociate into positive and negative ions (Equation 2). The cross-section for this process increases roughly linearly over a threefold range with increasing electron energies.\(^{(32)}\) However, there is no particular advantage to this process in mass spectrometric analysis and as a result it has found little practical use.

\[
\text{AB} + e^- (\sim 15\ eV) \rightarrow (\text{AB}^+) \rightarrow \text{A}^+ + \text{B}^- + e^- \quad (2)
\]

The potential energy surfaces for the formation of useful negative ions are shown in Figure 1. When an electron of low energy (0–10 eV) interacts with an electron-capturing molecule AB in the gas phase, it can undergo: nonresonant elastic scattering; inelastic scattering, which leaves the molecule in an excited state (Equation 3):

\[
\text{AB} + e^- (0–10\ eV) \rightarrow \text{AB}^+ + e^- \quad (3)
\]
or resonant attachment, wherein a temporary or transient negative ion (AB\textsuperscript{−}) or (M\textsuperscript{−}) is produced (Equations 4–6). If the kinetic energy of the incident electron goes solely into nuclear motion of the neutral molecule, long-lived molecular radical anions (M\textsuperscript{−}) (Figure 1) can be produced by nuclear-excited Feshbach resonance, with lifetimes that can be equal to or exceed the microsecond range (Equation 5)\(^{(33)}\) or the time-frame necessary for detection by mass spectrometry. In this type of resonance, there is no electronic excitation; the energy of the captured electron goes into molecular vibrations. Because of this excess energy, molecular ions formed by Feshbach resonance can decay by autodetachment, i.e. by loss of the electron and return to the neutral state (Equation 4), and the ion therefore would not be detectable by mass spectrometry. One of the purposes of the reagent or buffer gas in the ion source is to stabilize the molecular ion by removing excess energy via collisions.

\[
\text{AB} + e^- (0–10\ eV) \rightarrow (\text{AB}^+) \rightarrow \text{AB} + e^- \quad (4)
\]

\[
\text{AB} + e^- (~0\ eV) \rightarrow (\text{AB}^+) \rightarrow \text{AB}^* \quad (5)
\]

\[
\text{AB} + e^- (0.1–10\ eV) \rightarrow \text{A}^* + \text{B}^- \quad (6)
\]

A long lifetime \((T_a)\) also arises if the anion’s internal energy can be distributed over a large number of vibrational degrees of freedom \((N)\). A reasonable correlation between the lifetime and the electron affinity \((EA)\) was found for monosubstituted nitrobenzenes (Equation 7):\(^{(36)}\)

\[
T_a^{1/(N–1)} \propto EA \quad (7)
\]

This relationship was tested further by inclusion of the electron attachment rate constant \(k_a\) (Equation 8) to produce the molecular radical anion:\(^{(37,36)}\)

\[
(k_aT_a)^{1/(N–1)} \propto EA \quad (8)
\]

The correlation was not improved further and it was concluded that regardless of wide variations in \(k_a\) values there is no convincing correlation with the electron affinities nor, for that matter, any relationship with dipole moments or structural changes caused by the formation of the radical anion.\(^{(35)}\) The authors conclude that the initial step in resonance electron capture is a very poorly understood process.\(^{(7)}\)

Trapping of the incident electron by the molecule in its ground state can produce short-lived transient molecular radical anions with lifetimes that are generally less than the nanosecond range or as short as that of a single vibration.\(^{(35)}\) This type of electron–molecule interaction leads to shape resonances that are responsible for the production of most of the anion and radical fragments (Equation 6) observed in ECNIMS.
Figure 1 Hypothetical one-dimensional Born–Oppenheimer energy diagram showing the relationship between the capture of an electron by a neutral molecule (AB) and the production of a molecular radical anion (M\textsuperscript{−}) and fragment anion (B\textsuperscript{−}) via dissociative electron capture or metastable ion decomposition.

The overall process leading to A\textsuperscript{*} and B\textsuperscript{−} is shown as a purely repulsive potential energy surface (Figure 1), even though a shallow attractive state is present. The temporary or transient negative ions result from the attractive polarization between the neutral molecule and electron, and the repulsive force from the relative motion of the two bodies\textsuperscript{33,34}. A shallow well is created, hence the terminology “shape resonance”. The electron attaches and detaches by tunneling through the angular momentum barrier, and the height and thickness of this barrier determine the lifetime of the temporary negative ion. Orbital symmetry, resonance energy, and ion lifetimes are interrelated\textsuperscript{34}. Radical anions involving σ* orbitals are short-lived and generally produced with electrons of energies greater than 5 eV, as is the case for saturated hydrocarbons, whereas electron capture into low-lying antibonding π* orbitals have much higher angular momentum barriers to electron tunneling. These anions may be sufficiently long-lived to observe vibrational fine structure in ETS experiments\textsuperscript{31,34}. The electron affinities of neutral molecules are an important criterion in determining whether or not stable anions can be formed. The electron affinity is the energy difference between the electronic ground states of the neutral molecule and radical anion, each in its lowest vibrational mode. By convention, molecules that capture electrons and produce radical anions that lie energetically below the ground state of the neutral molecule have positive electron affinities, and those that form radical anions lying energetically above the neutral molecule have negative electron affinities\textsuperscript{3}. The former ions are sufficiently stable to be detected by mass spectrometry under normal ECNIMS operating conditions. Benzene, for example, has an electron affinity of \(\Delta H = 1.2\text{ eV}\)\textsuperscript{37,38} but the molecular ion is not observed by ECNIMS, whereas hexafluorobenzene has a positive electron affinity of \(\Delta H = 0.4\text{ eV}\)\textsuperscript{37} and produces an intense molecular ion peak with electrons of energies \(\sim 0.03\text{ eV}\).

A variety of different experimental procedures, theoretical methods, and semi-empirical approaches have been used to estimate electron affinities, but the values obtained are often in poor agreement with each other.\textsuperscript{37} Relationships between electron affinities and NIR states or lowest unoccupied molecular orbital (LUMO) energies (Equation 9) can be useful within a given series or class of compounds.\textsuperscript{37,39} The \(EA/\delta_{\text{LUMO}}\) relationship requires a constant, \(\delta\): the reorganization energy
correction term to account for the charge density readjustment when an electron is added to the molecule. Its value lies in the range 0–3 eV. A scaling constant $\xi$ is also required:

$$EA = -\xi \varepsilon_{\text{LUMO}} - \delta$$ (9)

The lower the LUMO energies, the more likely the neutral molecule will capture an electron to form a stable molecular radical anion. Conjugation and electron-withdrawing groups on molecules lower the LUMO energies and favor molecular ion formation.

Dissociative electron capture processes (Equation 6) are distinct categories of electron capture events that generally do not result from decomposition of a stable molecular ion. Although metastable ions do occur in negative ion mass spectrometry, the resonances for dissociative capture are energetically distinct from those that produce the molecular ions. As noted above, transient molecular radical anions produced via shape resonances are involved in dissociative electron capture events. Anions produced by dissociative electron capture (Equation 6) have another channel available for dissociation with a rate that is competitive with autodetachment. The dissociative electron capture cross-section, $\sigma_{\text{da}}$, is dependent on the cross-section for electron capture, $\sigma_0$, as well as on the time that it takes for dissociation to occur, $T_d$, versus the autodetachment lifetime, $T_a$ (Equation 10): (33)

$$\sigma_{\text{da}} = \sigma_0 \exp \left( -\frac{T_d}{T_a} \right)$$ (10)

When temporary negative ions are formed along repulsive potential energy surfaces, the ion lifetimes are short, i.e. $10^{-13} – 10^{-15}$ s. Most polyatomic molecules fall into this category. However, lifetimes extending to the microsecond range occur when the resonances are close to 0 eV, i.e. via Feshbach resonances. In this case the ions may undergo metastable decompositions (Figure 1), which involves redistribution of the energy and often molecular rearrangements. (30) Although dissociative electron capture processes do not require stabilizing collisions, (33) an optimum reagent gas pressure is required for maximum ion production. (7,15) This is because the dissociative electron capture process, like the molecular ion-forming process, is a resonance phenomenon.

Dissociative capture fragment ions may result from several resonance states. In addition to shape resonances, there are core-excited resonances in which electron attachment is accompanied by promotion of the molecule to an electronically excited state. (33) As a result of this promotion of the core electron, the core itself becomes positively polarized, which provides an attractive potential for the electron being captured.

The minimum energy required for the formation of any anion is the appearance energy, $\varepsilon_1$. Within the Born–Oppenheimer approximation, i.e. no nuclear motion when the electron is captured, the energy $\varepsilon_1$ is the difference in energy between the ground state, when the neutral molecule is at the relaxed classical turning point for nuclear motion, and the anionic surface (Figure 1). The Franck–Condon principle requires that transitions to the anionic surface occur only within the energy range $\varepsilon_1 - \varepsilon_2$. The position and shape of the anion yield curve for $B^-$ are simply a reflection of the neutral molecule’s wave function bounded by the slope of the anionic dissociative surface within the Franck–Condon region.

The dissociation limit or minimum heat of reaction ($\Delta H_0$) is the difference between the bond dissociation energy ($D$) of AB and the electron affinity ($EA$) of $B^*$ (Equation 11):

$$\Delta H_0 = D(A-B) - EA(B^*)$$ (11)

Unless there is electronic or vibrational predissociation in the precursor ion, (27) the dissociation limit lies below the portion of the anionic surface that is located within the Franck–Condon region. It is apparent that the relatively modest energy requirements for dissociative electron capture result from the high electron affinity of $B^*$. Thus, a large number of molecules in their electronic and vibrational ground states undergo dissociative electron capture processes despite $\varepsilon_1$ values (0–2 eV) that are much smaller than the bond dissociation energies $D(A-B)$. Dissociative processes for chlorinated compounds from ground electronic states, for example, may involve resonances that are less than 1 eV. Fluorine organics generally require higher electron energies because of the larger carbon–fluorine bond dissociation energies. But threshold energies $\varepsilon_1$ for fluoride ion production may be significantly smaller than the bond dissociation energies because of the high electron affinity ($EA = 3.45$ eV) of the fluorine atom. (37) The appearance energy $\varepsilon_1$ for fluoride ion from CF$_2$Cl$_2$, for example, is 1.8 eV (40) and the carbon–fluorine bond dissociation energy $D(C-F)$ is 4.93 eV. These values give $\Delta H_0 = 1.48$ eV. In addition to these low-energy pathways, most molecules have dissociative capture channels that involve higher energy states. Ions formed by electron capture can possess excess energy $\varepsilon_x$ (Equation 12). Thus, the fluoride ion produced from CF$_2$Cl$_2$ possesses 0.32 eV of excess energy, which is partitioned into translational and rotational energy or held internally as vibrational energy. (40)

$$\varepsilon_1 = \Delta H_0 + \varepsilon_x$$ (12)

Negative ions produced with electrons of energies $<$1 eV are generally more intense than those produced.
from capture of higher energy electrons. Generally, the cross-section for electron capture to form temporary negative ions depends on the relative thickness and height of the angular momentum barrier through which the electrons must tunnel, and these are greater for resonances close to 0 eV. The steepness of the repulsive potential surface also dictates the lifetime for autodetachment $T_a$ (Equation 10), which occurs only within the boundary of the neutral molecule potential energy surface. Once the internuclear distance is large enough to have passed the crossover point, $Q_c$ (Figure 1), autodetachment no longer occurs$^{(33,62)}$ and the temporary negative ion proceeds to the product species.

4 ELECTRON MONOCHROMATOR

4.1 Designs

Electrons from a hot filament possess an energy spread of 0–2 eV according to a Maxwell–Boltzmann distribution. By varying the filament potential, standard instruments can be used to generate slow electrons in the energy range 0–10 eV that are necessary for resonance electron capture. Such procedures have been used, for example, to study the NIR spectra of mixed anhydrides formed from fatty acids and trifluoroacetic acid$^{(41)}$ and a variety of myristic acid derivatives and their methyl esters.$^{(42)}$

Investigators who were interested in obtaining accurate values for the ionization potentials of atoms and simple molecules, however, recognized early on that the energy spread ($\pm 5$ eV) of electrons from a hot filament was unacceptable for this purpose. Hence, the need arose for sources with electron energy bandwidths of $<0.1$ eV. This need led to the development of a variety of electron monochromator designs long before their general utility in mass spectrometry could be appreciated. All early monochromators were designed to produce positive ions, and the production of thermal electrons was not particularly important. One early design utilized a magnetic field of about 10 G to disperse the electrons according to their energies.$^{(43)}$ It was, however, difficult to maintain a uniform magnetic field of this strength in the presence of stray magnetic fields. The electrostatic parallel-plate electron-energy selector$^{(44,45)}$ was simple in design, but massive room-sized Helmholtz coils were necessary to shield out stray magnetic fields. A 127° cylindrical electrostatic deflector$^{(46–48)}$ was one of the more popular early electron monochromator designs, because the foci of electron trajectories are located at the field boundaries. With this device, electron beams of 0.1 $\mu$A and energy bandwidths of $<0.1$ eV became available in the energy range 0–50 eV.$^{(47)}$ But space charging problems in these monochromators resulted in the addition of grids and electron-absorbing surfaces referred to as “electron velvet”. An early 180° hemispherical electrostatic deflector$^{(49)}$ avoided the use of slits in the entrance and exit planes, instead using electron lenses at high potentials. Space charging was thus reduced without using coatings and grids, although the strong deceleration of the electron velocities created its own set of undesirable effects. This instrument produced homogeneous electron beams with energy spreads of $<0.005$ eV but no improvement in beam brightness.

In all of these designs, the intensities of the electron beams produced were very weak and efforts to increase beam brightness could only be achieved at the expense of energy bandwidths that were much greater than those that would have been predicted on the basis of the filament temperatures.$^{(50)}$ Moreover, the performance of electrostatic analyzers is unpredictable when gases introduced into the target chamber modify the contact potentials of the electron optic elements.$^{(51)}$ Irregular beam transmission is also a problem when the target region is not shielded against stray electrostatic and magnetic fields. At low electron energies, this problem becomes even worse.

Hemispherical analyzers provide two-dimensional focusing and have a resolving power almost twice that of cylindrical analyzers of the same radius, but they must be operated at 1–3 eV.$^{(52)}$ A completely different approach for producing zero-energy electrons, referred to as reversal electron attachment detection,$^{(53,54)}$ involves focusing an electron beam into an electrostatic mirror to a plane where the electron translation is reversed, at which point the longitudinal electron energy is zero. Non-zero-energy electrons are captured along the longitudinal axis at some point beyond the reversal plane. The method was developed for ECNIMS, but it is difficult to obtain true energy monochromation and an electron beam that can produce significant abundance of ions with it.

As early as 1907, Thomson$^{(55)}$ recognized the advantages of using crossed electric (E) and magnetic (B) fields for determining the $m/z$ values of positive and negative ions generated under a variety of experimental conditions. The $E \times B$ field was configured with the initial beam trajectory oriented perpendicular to both fields. It was recognized that crossed electric and magnetic fields have perfect focusing that depends only on the $m/z$ value and not on the initial velocity or direction of the charged particles entering the analyzer.$^{(56)}$ By 1955 Fox had introduced a new electron gun that used electrodes to create retarding potential differences, and its original purpose was to reduce the energy spread of electrons in axial magnetic fields.$^{(57)}$ These devices were initially used to determine ionization potentials of rare gases,$^{(58)}$ but soon afterwards an electron monochromator was described$^{(59)}$ that utilized the insights of Fox to confine a low-energy
electron beam by an axial magnetic field and Thomson’s crossed electric and magnetic field to disperse simultaneously the electrons according to their kinetic energies. Electron monochromators utilizing the basic $E \times B$ field principle have gained some popularity for resonance electron capture studies in recent years.\(^{(27,29,30,61–63)}\)

In a typical monochromator design (Figure 2), electrons emitted from the filament (a) are focused by electrodes (b) into a deflection region (c) defined by the crossed magnetic field ($\mathbf{B}$) and electric fields ($\mathbf{E}$). The electrons within these crossed fields undergo trochoidal motion\(^{(56)}\) along the equipotential surfaces of the magnetic field lines according to their energies. The monochromatic electron beam emerges through an aperture from the deflection region (c) and is focused by electrodes (d) into the ion chamber (g). A small electric field ($\mathbf{E}$) of about $0.4 \text{ V cm}^{-1}$ in the deflection region (c) is established between a pair of deflecting plates oriented perpendicular to the electron beam, and a magnetic field ($\mathbf{B}$) of about $130 \text{ G}$ is oriented perpendicular to $\mathbf{E}$. The drift velocity ($v_d$) (Equation 13)

$$v_d = \frac{E \times B}{B^2}$$  \hspace{1cm} (13)

governs the electron energy ($E$) by displacing the electron beam of initial velocity $v_0$ a distance $D$ within the crossed field region of length $L$. The final electron kinetic energy is determined by the potential difference between the filament center and the ion reaction chamber. The electron energy can be controlled by varying $\mathbf{B}$, $\mathbf{E}$ or $v_0$.

The last one, which is controlled by the filament potential, is most convenient. This design is very successful because the electrons are confined without chromatic loss in the magnetic field, regardless of their energies. The axial magnetic field provides constant electron beam focusing throughout the energy range ($0–60 \text{ eV}$), thus eliminating focal adjustments during operation.\(^{(63)}\)

In addition to quadrupole analyzers,\(^{(27,29,30,61–63)}\) the electron monochromator has been adapted to sector instruments.\(^{(64–66)}\)

### 4.2 Performance

#### 4.2.1 Sensitivity

High analytical sensitivity in mass spectrometry begins with bright electron beams in the ion source. The prototype electron monochromator adapted to a quadrupole analyzer\(^{(61)}\) transmits an electron beam of $2 \mu\text{A}$ with an energy spread of $\pm0.1 \text{ eV}$ full width at half-maximum (fwhm). The usual trade-off between beam current and resolution is observed. By reducing the exit aperture size of the monochromator (Figure 2) as well as the electric field strength, the resolution can be improved. At $\pm0.07 \text{ eV}$ (fwhm) energy distribution, the transmitted current is $0.5 \mu\text{A}$.

With an electron energy setting of $0.03 \text{ eV}$, 50 pg of hexachlorobenzene effluent from a gas chromatograph can be detected with a signal-to-noise ratio of $\geq 20$. The Pierce element\(^{(67)}\) used in the prototype for the sector instrument yields electron beams of $430 \mu\text{A}$ at $0.03 \text{ eV}$ kinetic energy and gives a benchmark sensitivity of 1 pg of hexachlorobenzene.\(^{(66)}\) Further refinements by JEOL USA, Inc have produced detection limits of 10 fg at a signal-to-noise ratio of 30. The reasons for this lack of sensitivity are not clear at this time.

#### 4.2.2 Collisional Stabilization

The moderating gas introduced into the ion source for generating slow electrons also acts to remove the excess energy from the molecular ions and stabilizes them towards autodetachment (Equation 4).\(^{(6,7,36)}\) Because the EMMS instrument provides direct control over the energy of the ionizing electron beam, the moderating gas is not needed to thermalize the electrons, and collisional stabilization of the ions can be studied independent of the electron energies.

The lowest pressure (c. $6.67 \times 10^{-2} \text{ Pa}$ or $0.5 \text{ mTorr}$) attainable in the ion source when a gas chromatograph is used is limited by the residual gas flowing from the capillary column.\(^{(68)}\) Thus, a pressure change of helium from $6.67 \times 10^{-2} \text{ Pa}$ to $1.33–1.60 \text{ Pa}$ ($0.5 \text{ mTorr}$ to $10–12 \text{ Torr}$)

³ Not measured.

causes about a 20-fold enhancement in the molecular ion intensities (Table 1). The effect of this pressure difference on the dissociative attachment ions is essentially zero (Table 1) or, more likely, a small decrease in ion signal because of ion scattering. Further increase in helium pressure to 3.33 Pa (25 mTorr) raises the molecular ion intensities by only an additional 1.5-fold (Figure 3).

Different buffer gases, of course, have different effects on the stabilization of the molecular ions (Figure 3). Gases possessing internal degrees of freedom have a greater stabilizing effect. With the helium gas flowing from the gas chromatograph creating a pressure of 1.33–1.60 Pa (10–12 mTorr), added methane at about 1.1 Pa (8 mTorr) causes a further threefold increase in the intensity of the molecular ion of hexachlorobenzene. Similar but smaller increases in the molecular ion intensities are observed when isobutane, ethylene, carbon dioxide and hydrogen are added. Each of these gases shows an optimum pressure for ion stabilization, after which the intensities decrease because of ion scattering.

4.2.3 Electron Flux Variation with Added Buffer Gases

Ideally the electron flux should remain constant over the entire electron energy range (0–10 eV) of interest. In ECNIMS this aspect is entirely overlooked because it is impossible to obtain a constant flux of electrons at different energies without changing the reagent gas pressure. Typically, the electron energy distribution is ~50% near 0 eV, 5% between 0 and 0.15 eV, and 12% between 0.15 and 0.45 eV. With the EMMS system the problem is not nearly as severe. Experiments have shown that the electron current varies by a maximum of ±30% (~0.1 μA eV⁻¹) over the energy range 0–3.5 eV (Figure 4). The addition of carbon dioxide as a buffer gas...
reduces this variation to about \( \pm 22\% \) at pressures of 2.13 and 5.46 Pa (16 and 41 mTorr). But carbon dioxide in the ion source also reduces the absolute current by 30% at 2.13 Pa (16 mTorr) and 40% when the pressure is increased to 5.46 Pa (40 mTorr). Carbon dioxide is among the more effective gases for inelastic scattering of electrons. Most carrier gases for gas chromatography, particularly helium, would not cause as great a change in the electron flux. In general, these are insignificant losses in the electron beam.

Thermalization of the electron energies is also likely when buffer gases are introduced. In carbon dioxide, for example, the electron thermalization rate constant \( k_\text{e} \) is \( 5 \times 10^{-9} \text{cc s}^{-1} \), which is competitive with quenching of the ion excess energy \( k_\text{Q} = 1 \times 10^{-10} \text{cc s}^{-1} \).\(^{(69)}\) If buffer gases are needed for stabilization of molecular ions, the potential problem of resonance peak shifts due to electron thermalization can be countered by calibrating the electron energy with the buffer gas present. The effect of high pressures on electron energies as well as on ion stabilization is potentially more serious when samples are introduced through the batch inlet, because the amount of sample vaporized into the ion source cannot be controlled and the pressure is likely to vary unpredictably.

### 4.2.4 Electron Energy Ramping

The capture of electrons by molecules with positive electron affinities is a resonance process, and different anions require different electron energies for maximum signal production. To obtain complete negative ion spectra of compounds, broad distributions of electron energies must be available. When samples are analyzed with EMMS the electron beam must be ramped continuously and rapidly over the entire electron energy range required to produce the mass spectra. In studies with hexafluorobenzene\(^{(70)}\) the signal intensity was found to be 90% of the maximum value at a slew rate of 250 eV s\(^{-1}\) over a 10-eV electron energy range. At this rate 50 scans can be recorded of a 2-s-wide gas chromatographic effluent peak. The more difficult problem is to scan the mass range of the compound in this time-frame. There are perhaps several analyzers that could be used for this purpose, but the most practical will likely be the time-of-flight analyzer.

### 4.3 Analytical Information

#### 4.3.1 Discrimination between \( M^- \) and \( ^{13}C(M-H)^- \) by Resonance Electron Energies

Resonance electron energies can be used as an additional element of analytical resolution, this advantage has not been fully recognized in the past. For example, the mass-resolving power required to separate \( M^- \) from \((M-H)^-\) containing one carbon-13 at mass 215 is \( 4.8 \times 10^4 \) by conventional mass spectrometry. The herbicide atrazine (2-chloro-4-ethylamino-6-isopropylamino-S-triazine) has an ion with \( m/z \) 215 that could be due to either \( M^{35} \) or \( ^{13}C(M-H)^- \). Two \( \epsilon_{\text{max}} \) values of 0.38 and 1.78 eV appear in the electron energy scan of peak \( m/z \) 215,\(^{(61,62)}\) The latter peak is due to the \( ^{13}C(M-H)^- \) ion because the instrument also transmits a peak at \( m/z \) 214 due to the \( ^{12}C(M-H)^- \) ion with the same \( \epsilon_{\text{max}} \) value.

Previous reports attributing energy scan peaks with \( \epsilon_{\text{max}} \) values of 3.8 and 7.2 eV to molecular ion resonances for nitrobenzene\(^{(61,71)}\) are, in fact, due to the \( ^{13}C(M-H)^- \) ion.\(^{(72)}\) The peaks with maxima around 7 eV reported for molecular ions of polyaromatic hydrocarbons\(^{(61)}\) may also be due to the \( ^{13}C(M-H)^- \) ion.

#### 4.3.2 Two- and Three-dimensional Electron Energy-mass Spectra

NIRs for all resonance and dissociative electron capture processes can be plotted as a function of electron energy versus the ion current.\(^{(73)}\) Such plots represent the total electron capture cross-section or probability of electron capture \([P(e)]\) at any given electron energy \( e \) for the compound under study. Two- and three-dimensional presentations of the data\(^{(73)}\) readily show distinguishing spectral features for each compound as shown here for \( o \)-butylbenzyl phthalate (Figure 5) and \( o \)-diethyl phthalate (Figure 6). Overlapping resonances can be deconvoluted with standard non-linear curve-fitting algorithms. Automated scanning of both the mass/charge ratio and the electron energies has not been achieved, but it should be possible using ion storage devices or time-of-flight mass analyzers.

#### 4.3.3 Isotope Effects

Apparent chloride ion isotope effects have been reported.\(^{(74)}\) More recently, the analysis of chlorine-37-enriched compounds \( 2[^{37}Cl]_3 \)- and \( 1[^{37}Cl]_4 \)-dichlorodibenzo-p-dioxin by standard ECNIMS methods using methane buffer gas was found to result in 1–3% greater loss of the lighter isotope.\(^{(75)}\) Using EMMS the loss of chloride ion from each of the positions in the two compounds was found to be nearly equally probable.\(^{(75,76)}\) Lower chlorine-37 ion yields in ECNIMS experiments may be due to a lower diffusion coefficient of the heavier isotope in the presence of buffer gas, which gives the ion more time in the ion source to undergo ion–ion or ion–wall reactions.\(^{(62)}\)
Figure 5 Two- and three-dimensional plots of o-butylbenzyl phthalate electron capture negative ion spectra: (a) three-dimensional electron energy versus ion mass/charge versus ion relative intensity; (b) two-dimensional electron energy versus ion mass/charge spectrum.
4.3.4 Electron Energy-dependent Regioselectivity

The EMMS system is ideally suited to study the regiochemistry of dissociating anions with respect to their electron attachment energies. Regiospecific labeling of compounds with stable isotopes and mass selection of the appropriate isotope provides a method for studying the energetics of regiochemical dissociation, as well as a potentially powerful method to follow the fate of compounds in metabolism and bioremediation studies.

The regioselective loss of the nitro groups from $p$-$^{15}$NO$_2$-labeled trinitrotoluene (TNT) occurs with electrons of 0.15 eV for the $p$-nitro group, whereas the loss of the $o$-nitro groups occurs at higher electron energies. The analysis of regiospecifically chlorine-37-labeled polychlorodibenzo-$p$-dioxins (PCDDs) showed that the more highly substituted ring is the more likely one to lose a chloride ion (Table 2). This is not an unexpected result, because there is steric relief in the resulting aromatic radical and some stabilization from the remaining chlorines.
These studies also showed an electron energy dependence for the regioselective loss of the chloride ion under dissociative electron capture conditions. The best examples for this regiochemical dependence are provided by the data for 1,2,3,7,8-pentachloro- and 1,2,3,4,7,8-hexachlorodioxins, both of which show the highest loss of chlorine from the 1-position with electrons of energy 0.03 eV and less chlorine loss from this position with electrons of higher energies. For the pentachlorodioxin isomer, more chlorine at the 3-position is lost at higher electron energies, whereas more chlorine is lost from the 7-position of the hexachlorodioxin isomer. In almost every example the chlorines at the 2-position are least sensitive to changes in the energies of the ionizing electrons. The explanation for the regiochemistry lies in the relative magnitude of the antibonding orbital densities in the electronic states where the electron becomes localized. However, an analysis of transition-state models of the transient radical anion is needed for any reliable explanations. An analysis of the transition states by open-shell calculations would be most helpful, but it is difficult to find sufficiently flexible basis sets in which the wavefunction does not degenerate to the neutral molecule and free electron.

Studies with regiospecifically labeled compounds by standard ECNIMS methods showed that regioselective chloride ion loss closely matched those results observed at 0.03 eV with EMMS. The results were consistent with expectations for the interaction of a high population of thermal electrons under reagent gas thermalization conditions. Comparisons of this type are potentially useful for developing an understanding of the ionization process under standard ECNIMS conditions.

### 4.4 Electron Capture Negative Ion Mass Spectrometry of Compound Classes

#### 4.4.1 Pesticides

4.4.1.1 Organophosphates Spectra of phosphorothioates produced with EMMS are generally rich in fragment ions but the spectra of phosphates are much less so.\(^{(73,77)}\) A comparison of the experimental electron attachment energies for phosphorothioate molecular ions with those obtained by a linear scaling relationship based on calculated LUMO energies shows surprisingly good agreement (Table 3).

A common fragment observed for the phosphorothioates listed in Table 3 is the loss of an ethyl radical (Scheme 1).\(^{(77)}\) The production of \((M - Et)^{-}\) ions occurs at electron energies that are typically higher than those that produce the molecular ions, and most phosphorothioates have two resonance states from which these ions are formed. The current view (see discussion in section 4.5) for the formation of these ions is that the ionizing electron is captured into a \(\pi^{*}\) state with a \(\sigma^{*}\) state involving a phosphate oxygen, the ethyl radical cleaves. Only through this \(\pi^{*} - \sigma^{*}\) interaction can such groups be cleaved by a symmetry-allowed process.

Phosphorothioates exhibit the formation of both phenolic and thiophenolic fragments under electron capture conditions in the EMMS system. These ions are frequently produced from several resonance states over a relatively broad range (0.3–9 eV) of energies. The thiophenolic fragments must be formed after a rearrangement, perhaps through a spiro intermediate, whereas the production of the phenoxide ion could

Scheme 1

Scheme 2

occur via a simple cleavage between the phosphorus and oxygen atoms. The electron energies for the formation of these ions are different, hence, the mechanisms for their formation must be different as well. A simple cleavage reaction that produces phenoxy ions, in contrast to the rearrangement mechanism that forms thiophenoxy ions, is supported by the observation that the former occurs with electrons of higher energies. Simple cleavage reactions generally are higher energy processes.

Phosphate and thiophosphate anions are frequently the most intense ions in the EMMS spectra of organophosphorothioates. These ions are produced over a relatively broad range (0.63–4.91 eV) of electron energies. The mechanism of production of these ions may be different from those that produce the (M − Et)\(^-\), thiophenoxy and phenoxy ions. The association of the electron with the $\pi^*$-orbital of the phosphate group and $\pi^*-\sigma^*$ mixing that allows cleavage to produce the phosphate group and phenyl radicals (Scheme 2) is supported by ab initio calculations.

A number of other common ions are observed in this series of compounds, including (M−Et−X)\(^-\), (M−OEt)\(^-\), and (M−OEt−X)\(^-\) ions, many of which are of lower intensities. Some unusual ions observed for organophosphorothioates containing a p-nitro group are C\(_3\)H\(_2\)NO\(^-\) and C\(_3\)H\(_4\)NO\(^-\) ions. The relatively large numbers of ions produced, as well as the aromatic cleavages observed for the nitro compounds, may be due to the close spacing of many low-lying orbitals, resulting in a large amount of orbital mixing that gives rise to complex fragmentations.

4.4.1.2 Carbamates Three common negative ions have been observed for all the carbamates studied. The molecular ions generally arise from one resonance state, but may involve two states (Table 4). There are no obvious characteristics about these molecules that
would distinguish those that form molecular ions from one state versus those that form the ions from two states.

A common carbamate anion (m/z 74) and an (M – 58)⁻ ion that arises through loss of the acylamido radical (CH₂NHC=O) from the parent molecule make up the important dissociative attachment ions. The energies for these processes are different, but the energies for the first NIRs tend to follow each other, i.e. carbamates with these processes are different, but the energies for the carbamate ions (M⁻) generally arise from only one NIR, whereas the (M – 58⁻) ions result from several states. Multiple resonances are generally associated with ions that have a large number of channels for deposition of the excess energy.²⁷,²⁹

4.4.1.3 Sym-Triazine Herbicides Numerous adduct ions, including (M + 1)⁻, (M + 2)⁻, (M + 4)⁻ and (M + 28)⁻ and, for compounds containing chlorine, (M + 35)⁻, are reported to have significant intensities in standard ECNIMS spectra of 3-triazine herbicides.²⁸ The abundances of these ions vary widely depending on the source temperature, pressure and source cleanliness. There are no adduct ions when these compounds are analyzed with the EMMS system. Although not many 3-triazines have been analyzed, the information that is available suggests that there may be considerable differences in the number of NIRs that produce specific fragment ions. The molecular ions for atrazine (2-chloro-4-ethylamino-6-isopropylamino-5-triazeine) and ametryne (2-ethylamino-4-isopropylamino-6-methyl-5-triazine), for example, arise from two states of similar energies, but the (M – H)⁻ ion of the former arises from one state (εmax, 1.97 eV) and that of the latter arises from four states in the electron energy range 0.35–9.20 eV. Such diverse electron energy scan patterns could be useful for distinguishing these compounds.

4.4.2 Environmental Compounds

Standard ECNIMS spectra of environmental compounds using reagent gases for electron thermalization have been published elsewhere.²⁷ The negative ion spectra include those of haloalkanes, halo- and nitro-aromatics, PCDDs, polychlorodibenzofurans, polychlorobiphenyls, alkyl phthalates and many others, and the interested reader is referred to this excellent source.²⁷ The following discussions are limited to those compounds for which data have been obtained using EMMS.

4.4.2.1 Polychlorodibenzop-dioxins

The electron capture negative ion mass spectra recorded with EMMS for PCDDs show only a few peaks.²⁷,²⁹ Higher chlorinated PCDDs show a single resonance for the molecular ion peak in the electron energy range 0.12–0.20 eV. Dichlorodibenzop-dioxins and some trichlorodibenzop-dioxins show no molecular ions. When the electron energy is scanned over the range 0–10 eV with the mass set to record the chloride ion, two broad peaks are observed for all PCDDs with maxima around 0 and 4 eV (Figure 7). The low-energy peak appears to be a composite of at least two peaks.

4.4.2.2 Polychlorobiphenyls

PCBs have been analyzed with GC/EMMS by monitoring the chloride ion peak produced with electrons of 0.03 eV energy.²⁷ The lower chlorinated PCBs show no molecular ions when analyzed with EMMS. Some pentachloro-²⁷ and even

a Data from Laramée et al.²⁶²
tetrachloro-PCB isomers, but generally at least six chlorines are necessary on the molecule before a molecular ion is observed. It is also of interest that 3,3',5,5'-tetrachloro-PCB displays a molecular ion, whereas PCBs with chlorine on the ortho positions generally do not. Molecular orbital (MO) calculations at the PM3 level show that the benzene rings of the 3,3',5,5'-isomer are coplanar with a low-lying π-orbital throughout the entire molecule. The PCB isomers with chlorines in the ortho position act more like two independent benzene rings and require more chlorines in either ring for the molecular ion to be observed.

The PCBs substituted in the ortho positions produce mainly chloride ions in EMMS, with electron energies for the first negative ion states ranging from 0.34 to 1.07 eV (77) for the ortho-substituted PCBs. In addition to the molecular and chloride ions, PCBs may also produce (M–Cl)−, (M–Cl2)−, and (M–H)−. (62,79)

4.4.2.3 Chloronaphthalenes Few electron energy scans have been recorded for chloronaphthalenes, but the potential for isomer distinction is suggested by the different profiles for the molecular ions from 1,4,6,8- and 1,4,7,8-tetrachloronaphthalenes. Broad and nonsymmetrical peaks are observed with maxima around 0.4 and 0.6 eV.

4.4.3 Organofluorine Compounds

4.4.3.1 Fluoroarenes Fluorinated compounds have been studied extensively with the EMMS system. The behavior of fluorinated compounds is not always predictable. Some distinguishing features in the spectra of fluorinated compounds include the general absence of molecular ions, the much higher than average electron energies required for production of the dissociative capture ions, and the very low cross-sections for dissociative electron capture in comparison to other compounds. Only hexafluorobenzene among the fluorinated aromatic compounds forms a long-lived detectable molecular ion, and this ion is formed with electrons of very narrow energy spread near 0 eV. Isomeric fluorobenzenes undergo dissociative capture with electrons of energies in the range 3–10 eV. Most states lie between 8 and 10 eV. The fluoride ion is observed mainly in this region, whereas the (M–H)− ion is formed in the energy range 2–4 eV. Many of the isomers yield fluoride ions by ion pair formation, as shown by the continuous increase in product ion with increasing energies above 14–16 eV.

The NIRs for dissociative electron attachment of isomeric di-, tri-, and tetrafluorobenzenes are distinctly different for each isomer. Thus, 1,2,4,5-tetrafluorobenzene has resonances for F−, C6H3F2−, and C6H3F4− that are as much as 1 eV lower than those required for the production of ions from 1,2,3,5-tetrafluorobenzene. The symmetrical isomer 1,3,5-trifluorobenzene, in comparison to 1,2,4-trifluorobenzene, shows a simpler mass/electron energy map and the resonance peaks are more symmetrical.

4.4.3.2 Unsaturated Cyclic and Alicyclic Fluoro Compounds The negative ion spectra of the structural isomers hexafluoro-1,3-butadiene, hexafluoro-2-butyne and hexafluorocyclobutene show significant differences in the abundance of various ions in the energy range 0–14 eV. Most of the ions above 2 eV are weak in intensity, as expected, but single peaks for the molecular ions, CF3− and C6F5−, and the clearly resolved peaks for fluoride ion and C2F3− from several different negative ion states were recorded over the entire energy range. In the lower electron energy region, hexafluoro-2-butyne and hexafluorocyclobutene show molecular ions but hexafluoro-1,3-butadiene does not. On the other hand, hexafluoro-1,3-butadiene produces an intense fluoride ion at 2 eV, a weaker one at 1 eV and a C1F4− ion at 1 eV, whereas hexafluoro-2-butyne produces only a weak fluoride ion at 2 eV and hexafluorocyclobutene produces neither ions. These results point out that the three structural isomers might possibly be differentiated by their electron energy scans.

Electron transmission spectra of the fluoroethylene series show that increasing fluorine substitution results in higher electron attachment energies, indicating that there is increased destabilization of the π* states. Solution-phase reduction indicates just the reverse, i.e. that it is easier to reduce the more highly
flourinated compounds. The results are rationalized on the basis that solution-phase reduction involves the geometries of the relaxed anion, whereas gas-phase electron–molecule interactions involve neutral molecule geometries.

4.4.3.3 Chlorofluoroalkanes Chlorofluoromethanes yield a series of negative ions over the electron energy range 0–6 eV. The common ions from CCl\(_3\)F, CCl\(_2\)F\(_2\) and CClF\(_3\) are F\(^-\), Cl\(^-\) and ClF\(^-\). Chloride ion is produced in greatest relative abundance from dissociative electron attachment, even where statistical considerations would dictate otherwise. For example, the relative intensities of the Cl\(^-\) and F\(^-\) peaks from CCl\(_3\)F, CCl\(_2\)F\(_2\), and CClF\(_3\) are in the ratio 200:7.25:5. According to semi-empirical modified intermediate neglect of differential overlap (MINDO) calculations, the lowest \(\sigma^*\) MO involves a C–Cl bond. The bond order for C–Cl decreases with the accommodation of the extra electron, which leads to a direct electronic dissociation to give the chloride ion. On the other hand, the bond order for C–F does not decrease upon capture of a low-energy electron. Typically in the case of mixed halogens, the electron goes to the \(\sigma\)-orbital and associates with the halogen having the greater “electron capacity”, which increases on going down the periodic table. This accounts for the tendency of these molecules to undergo dissociative electron capture with loss of a fluorine rather than a chlorine to give CClF\(_2\)^-, CCl\(_2\)F\(^-\) and CCl\(_3\)^- from the respective parent molecules. Chlorofluoromethanes with relatively more fluorines have higher appearance energies for production of the ions.

4.4.4 Organic Chemicals

4.4.4.1 Phthalates The interaction of low-energy electrons with phthalic anhydride and arylphthalalides has been reported. More recently, a study of one \(\text{meta}\) and seven \(\text{ortho}\)-phthalates was conducted in detail using GC/EMMS. Two NIRs are generally observed for each ion, with the molecular radical anion maxima appearing at electron energies ~0.6 and ~1.1 eV. Higher energy electrons produce the molecular ion (Scheme 3). These fragmentation pathways almost always are associated with their own unique resonances. In several instances the fragmentation involves the same \(E\) value as that which produces the molecular ion. This indicates metastable ion decomposition. \(m\)-Dimethyl phthalate yields a molecular ion with electrons of energies 0.19 and 0.87 eV, but no fragment ions.

4.4.4.2 Sulfonamides Sulfonamide antibiotics are a class of compounds structurally related to sulfanilamide. These compounds are used extensively in pharmacy and agriculture as antimicrobial agents. Molecular ions are observed for the largest of the sulfonamides, i.e. sulfabenzamide, sulfamethazine, and sulfisomidine. The major negative ion product from all underivatized sulfonamides in spectra taken using EMMS is the 4-aminobenzene sulfonate anion. Standard ECNIMS experiments, on the other hand, produce two major ions: the sulfonate ion, \(m/z\) 156; and an ion with one less hydrogen, \(m/z\) 155. Apparently, the reagent gas participates in the abstraction of a hydrogen atom from...
Figure 8 Electron energy scan of the m/z 156 fragment ion of sulfabenzamide.(77)

The parent compound or from the benzene sulfonate ion. Deconvolution of the main electron energy scan peak (Figure 8) suggests that there are two resonances responsible for the formation of the sulfonate anion from sulfonamides (Table 5). The electron energy required to form this ion lies in the range 0.15–0.70 eV for the first peak and 0.70–1.1 eV for the second peak.

The effects of electropositive and electronegative derivatizing groups on the negative ion spectra are clearly shown in this series of compounds. Silylation of sulfonamides results in fewer ions in the spectra. Only four of the derivatives show any ions at all (Table 5) and the spectra are generally weak when compared with those of the underivatized compound. Weak spectra are also observed under standard ECNIMS conditions. Trifluoroacetylation of the analinium nitrogen, on the other hand, yields derivatives that give much more intense signals under both standard ECNIMS conditions or when recorded with the EMMS system. The formation of fluorinated derivatives frequently gives good signals but no distinguishing features in the spectra of the different compounds, because the strongest peak in the spectrum is due to the derivatizing group anion. The most intense peaks in the EMMS spectra of trifluoroacetamide derivatives of sulfonamides, however, result from cleavage of the sulfonamide bond to give the 4-trifluoroacetylaminosulfonate anion (m/z 252). Deconvolution of the broad electron energy scan peak indicates that there are two resonances – one around 0.1 eV and another closer to 1 eV – for nearly all the trifluoroacetylated sulfamides (Table 5). Very weak resonance peaks can also be discerned in the range 3–4 eV for most of these derivatives.

4.4.4.3 Chloroethylenes The most abundant ion produced from chloroethanes and chloroethylenes under ECNIMS conditions is the chloride ion.(33) Other ions formed are (M–Cl)− and Cl2−. The electron energy plots for chloroethylenes show some interesting patterns in the resonance energies. For example, chloride ion loss generally occurs at higher resonance energies when chlorine substitution is lower (Table 6). This pattern is just the opposite to that observed for the ETS spectra of fluoroethylenes,(82) assuming that fluoride ion is the product from interaction of the electron with the parent molecule. There are too few examples for a general conclusion about geometrical isomerism, but geminal...
substitution of chlorines (Table 6) seems to result in a common resonance appearing around 0.19 eV.

4.4.4.4 Other studies An interesting mechanistic study involving methanol, deuteriomethanol, and allyl alcohol was undertaken with EMMS to examine hydrogen scrambling during dissociative electron capture. The calculated minimum heats of reaction (ΔHθ) for producing OH−, O2− and CH3O− are 2.1, 2.4 and 2.9 eV respectively. Experimentally, the methoxide ion shows three resonance peaks above 5.5 eV, whereas hydroxide and oxide ions show only a single resonance peak with Emax = 10.5 eV. Labeling studies show scrambling between OH− and OD−, but none for the production of methoxide ion, which indicates direct O−D bond cleavage. The MINDO results indicate high-lying orbitals with mixed σ* states. These results have been interpreted in terms of a core-excited resonance at 10.5 eV to account for the hydrogen scrambling experiments. The OH− and C2H3O− ions from allyl alcohol occur with Emax = 1.7 eV. Calculations by the MINDO method indicate that a π*-orbital is involved in the production of these anions. Ethylene captures electrons near 1.8 eV, which is about the same as that for allyl alcohol.

Resonance electron capture processes are important in a variety of other scientific areas. The electron capture detector used in gas chromatography, for example, depends very much on the gas-phase ion chemistry that can be elucidated by studies carried out with EMMS and vice versa. Thus, the pulsed electron capture detector can be elucidated by studies carried out with EMMS and its hybrid, the photodetachment-modulated electron capture detector, are among the few tools available and its reverse. Thus, the pulsed electron capture detector used in gas chromatography, for example, depends very much on the gas-phase ion chemistry that can be elucidated by studies carried out with EMMS and vice versa. Therefore, the pulsed electron capture detector, are among the few tools available.

4 Relative chloride ion current in arbitrary units.

4.4.5 Derivatization Reactions

The ECNIMS methods can be extended to analyze compounds with active hydrogens by simply derivatizing them with electronophores. Derivatizing groups containing large numbers of fluorine atoms are very popular because of the excellent sensitivity that results when electrons are captured by these groups under ECNIMS conditions. For example, perfluoroacetyl, pentafluorobenzyl, pentafluorobenzyl, and (pentafluorophenyl)methanimine derivatives of chlorophenols and choroanilines produce analyte-specific anions under ECNIMS conditions. Hammel linear free energy relationships have been found useful for predicting a variety of properties, including the relative intensity of the molecular ion and the direction of fragmentation. 3,5-Bis-trifluoromethylbenzoyl derivatives of mono- and dihydroxy-steroids have been prepared to give improved sensitivity and chromatographic behavior in ECNIMS studies. Derivatization of active hydrogens by electronophores is particularly important in biomedical applications and the analysis of drugs.

Pentafluorobenzyl chloroformate, for example, has been used to derivatize amino acids in biological fluids for subsequent detection by ECNIMS in the femtomolar range. DNA oxidative damage quantified via the pentafluorobenzyl-tert-butyldimethylsilyl derivative of 2-methylglycerate released from 2-thymidine glycol can be detected with just 41 amol injected onto the column by gas chromatography/electron capture negative ion mass spectrometry (GC/ECNIMS). Pentafluorobenzylaion of L-tryptophan and its acidic metabolites in studies on infectious and inflammatory diseases allows their detection in the femtogram range by GC/ECNIMS and in the low picogram range by liquid chromatography/electron capture negative ion mass spectrometry (LC/ECNIMS) using particle beam transfer.
The simplicity and effectiveness of derivatization reactions, together with the inherent specificity and sensitivity of ECNIMS methods, should become even more powerful when the analyses are performed with EMMS because of the extra analytical dimension available. The effectiveness of the analysis of sulfonamides after derivatization has already been noted (Table 5). The Schotten–Baumann reaction involves a very simple procedure that can be used to derivatize the active hydrogens of hydroxyl, sulfhydryl, amino, and phosphonic acid groups (Equation 14) by shaking the compounds of interest with pentafluorobenzoyl chloride in aqueous media at room temperature. Three-dimensional plots of these derivatives obtained with GC/EMMS are relatively simple but sufficiently different that they can be used for rapid screening of compounds that might be more difficult to analyze by standard EMMS methods (Figure 9).

\[
RZH + C_6F_5COCl \rightarrow C_6F_5COZR + HCl
\]
\[
ZH = -OH, -SH, -NH, -NH_2, -P(O)OH
\] (14)

Examples of other potentially important applications of these methods include the analysis of fatty acids, which are characteristic structural components of bacterial lipopolysaccharides, tell-tale long-chain fatty alcohols from mycobacterial infections, including tuberculosis, and small amino acid neurotransmitters. Dipicolinic acid is a chemical unique to bacterial spores that produces strong negative ion signals. The negative ion mass spectra of spores are, however, complicated by the presence of extraneous ions whose appearance is tied to the degree of sporulation in a given culture, and to slight changes in the ion source pressure and temperature. The appearance of spurious ions in ECNIMS is a common problem that is exacerbated by the introduction of whole bacteria into the mass spectrometer. These artifacts were eliminated when the electron monochromator was used to supply electrons with energies specific for electron capture by dipicolinic acid. Derivatized *Bacillus globigi* spores produced an intense peak of signal-to-noise greater than 20 corresponding to 300 spores.

4.4.6 Explosives

An area that can benefit from using EMMS is explosives detection. The extra dimension of information provided by resonance electron energies should help greatly in the early detection of these compounds. In many cases, it may be possible to identify common explosives by simply scanning the electron energy for the nitro \((m/z 46)\) anion (Figure 10).\(^{62,107,108}\)

TNT possess two types of \(C-NO_2\) bonds: a resonance peak for loss of the \(p\)-nitro group near 0 eV and a broad peak centered around 3.5 eV. The nitrate ester, pentaerythritol tetranitrate (PETN), contains an O–NO\(_2\) bond and shows just a single resonance peak around 0 eV for loss of the nitro group. 1,3,5-Trinitro-1,3,5-triazocyclohexane (RDX) contains nitramine bonds (N–NO\(_2\)) and shows \(\epsilon_{\text{max}}\) values of 0.3, 4.5, and 9.4 eV. The experimentally observed resonances for loss of the nitro groups in these three compounds are distinctive and they could easily be used to identify them even

---

**Figure 9** Pentafluorobenzoyl derivatives of: (a) 2,2-thiodiethanol; (b) \(N, N\)-dimethylamino-2-ethanthiol; (c) pinacolyl alcohol.
without any other mass spectral information or gas chromatography retention times.

These explosives can also be distinguished from some common nitro-containing compounds on the basis of the electron energy scans. Nitrobenzene, a component of domestic products, for example, is easily distinguished from RDX, PETN, and TNT just by the nitro anion resonances around 1 and 4 eV. Nitrobenzene also shows several strong resonances for the phenyl anion at 3.6 and 6.0 eV\(^{61}\) and one for the molecular ion around 0.06 eV\(^{61,72}\). 2-Nitropropane, a combustion product, has three observable resonances at 0.68, 4.56, and 7.88 eV. These values are sufficiently different from those of the explosives and especially of RDX that it is unlikely that they would be identified incorrectly. The peak shapes are also quite characteristic and could be used for

---

**Figure 10** Electron energy scans of the nitro group anion of: (a) 2,4,6-trinitrotoluene (TNT); (b) pentaerythritol tetranitrate (PETN); (c) 1,3,5-trinitro-1,3,5-triazocyclohexane (RDX); (d) nitrobenzene; (e) nitropropane\(^{62}\).
identification. If mass measurements are included, then positive identifications are greatly enhanced, because most nitro-containing compounds also show resonance peaks for the molecular ion and other fragments. Portable EMMS systems for explosives detection would require “sniffing devices” for collection and concentration of the vapors. When time is not the primary consideration, GC/EMMS could be used for the extra dimension and certainty of identification.

4.5 Mechanisms in Electron Capture Negative Ion Mass Spectrometry

The interpretation of mechanisms in ECNIMS has been largely based on models wherein a molecular radical anion is formed and, through classical electron pushing, fragmentations could be postulated. The distinction between fragmentation that occurs in the ion source and metastable decompositions that occur after the ion has been accelerated has been recognized from the outset. Metastable ion decompositions may involve cleavages with or without molecular rearrangements or composite decompositions that involve both simple cleavage and rearrangement followed by cleavage. Collision-induced dissociations can be used to enhance the fragmentation processes for parent ions with low internal energies. Mechanistic studies wherein decompositions take place from even-electron ions such as \((\text{M}–\text{H})^-\) can be produced by secondary ion mass spectrometry or fast atom bombardment mass spectrometry and used for understanding fragmentations apart from the electron capture process itself. Radical anions may also undergo competing ion/molecule reactions that include electron transfer, proton transfer, hydrogen atom abstraction, and nucleophilic substitution processes, from which much can be learned about the relative acidities, electron affinities, reactivities, structures and whether such species behave more as anions or as radicals. A particularly interesting and useful process is the dissociative electron attachment to \(\text{N}_2\text{O}\), which yields \(\text{O}^-\). This interesting and useful process is the dissociative electron capture, however, may not be quite as simple as once thought, because the states that produce observable molecular ions are often, if not usually, different from those that produce the fragment ions. The production of stable molecular ions that are long-lived enough to observe in the mass spectrometer almost certainly requires the presence of \(\pi\)-orbitals, whereas fragmentation may involve either \(\pi\)- or \(\sigma\)-orbitals. In the following sections some details on mechanisms of resonance electron capture processes that can be extracted from combined studies involving MO calculations with high-level basis sets are described, along with data from an EMMS instrument.

4.5.1 Electronic States

There have been a number of studies showing linear relationships between calculated virtual orbital energies using Koopmans’ theorem and the experimental resonance electron attachment energies of organic molecules. Strong correlations between electron attachment energies for aromatic compounds obtained from ETS data and the virtual orbital energies calculated by Gaussian basis sets have been reported. An extension of this approach with data for PCDDs was also highly successful. Assuming neutral ground-state geometries for both the molecular ions and chloride ions, a correlation was found between \(\pi\) virtual orbital energies calculated by the B3LYP/D95 level of theory and the values for the resonances of the PCDDs obtained with EMMS and those for substituted benzenes from ETS (Figure 11). These correlations suggest that all negative-ion-forming processes for this class of compounds result from the \(\pi^*\) state. The loss of the chloride ion directly from the \(\pi^*\) state is a symmetry-forbidden process. Hence, there must be \(\pi^*-\sigma^*\) mixing in the transition state of the dissociating PCDD ion.

Through-space symmetry-allowed interactions between \(\pi^*\) and \(\sigma^*\)-orbitals have been proposed for dissociative attachment of chloride ion from chloronorbornyl and other chlorinated multicyclic ring systems. The loss of chloride ions from planar molecules such as vinyl chloride or chlorobenzenes in which the chlorine is attached directly to the olefinic system have
been postulated to involve out-of-plane distortions\textsuperscript{(119)} of the carbon–chlorine bond or a “bent-bond” model\textsuperscript{(120)} in the transition state. Studies with halobenzyl halides have shown strong $\pi^*-\sigma^*$ mixing as the phenylic carbon–halogen bond stretches.\textsuperscript{(121)} Thus, it is concluded that whenever an aromatic system is available, the dissociative attachment chemistry has a high probability of involving a $\pi^*$ state.

The resonance for chloride ion loss from PCDDs around 4 eV (Figure 7) has a precedent in the halobenzyl halide series,\textsuperscript{(121)} where resonances were observed around 4.5 eV. This peak is considerably more intense than the peaks resulting in phenylic chloride ion loss.\textsuperscript{(121)} A diffuse totally symmetrical s-orbital of the parent singlet excited state ($\pi, \pi^*$) was proposed. This state is symmetrical with respect to the aromatic ring and a transition to the $\sigma^*$ state is symmetry-allowed, thereby yielding a relatively intense peak.

### 4.5.2 Steric Requirements

The dissociative electron capture events that lead to the production of (M–R)$^-$ fragments from o-phthalates is driven by steric interactions that force the ester functionalities into noncoplanar orientations with the benzene ring.\textsuperscript{(86)} As the alkyl substituents become larger, the electron energy necessary to promote fragmentation decreases. Semi-empirical calculations, in fact, show that the optimum geometry for m-dimethyl phthalate has both ester groups coplanar with the benzene ring, whereas the ester groups are displaced by an average of 85° and 11° from coplanarity for the two groups in the o-phthalates. m-Dimethyl phthalate, as noted earlier, yields only a molecular ion by resonance electron capture.

Because the ionizing electrons are captured by the $\pi$-orbitals of the benzene ring, $\pi^*-\sigma^*$ mixing is necessary for fragmentation. The alkyl oxygens of o-phthalates are orthogonal to the plane of the benzene ring, thereby allowing efficient mixing of the $\sigma^*$-orbital of the oxygen with the $\pi^*$-orbital of the benzene ring. In m-phthalates the alkyl oxygens lie in the plane of the benzene ring where through-space orbital mixing is not possible and fragmentation cannot occur. The long-range $\pi^*-\sigma^*$ orbital mixing observed for the o-phthalates that results in the loss of alkyl radicals is similar to the interaction reported for the loss of the benzyl halide in halobenzylhalides.\textsuperscript{(121)} The cross-section for the halide ion arising from the benzylic position is several orders of magnitude greater than that for the halide ion arising from the phenylic position.\textsuperscript{(121)} The freely rotating benzylic C–X bond facilitates through-space $\pi^*-\sigma^*$ interaction, giving high yields of halide ion, whereas out-of-plane distortion of the phenylic C–Cl bond is necessary for $\pi^*-\sigma^*$ mixing and bond cleavage. The rigid constraints imposed by the geometry result in a much lower yield of phenylic halide ion.

An exact analogy for this mechanism was observed for the dissociative loss of the benzylic radical from benzylbutyl phthalate, which is consistent with the ionizing electron becoming localized in the benzyl group.\textsuperscript{(80)} This system does not fit the expected trend for steric crowding displayed by the o-dialkyl phthalates where the ionizing electron must first be associated with the benzene ring. These distinct $\pi$ systems, wherein one system fails to fit the trend of steric crowding during dissociative electron capture, provide added support for the separate roles of electronic and steric factors in dissociative electron capture processes.

#### 4.5.3 Hammett Relationships

Relationships between the $\varepsilon_{\text{max}}$ values and Hammett substituent constants for organophosphorothioates have been observed.\textsuperscript{(62,77)} An excellent correlation has been demonstrated for the electron energies required to produce (M – Et)$^-$ with Hammett substituent constants (Figure 12). The fluoro compound, however, does not fit the correlation. This compound is also the only one that has an electron energy maximum for the production of (M – Et)$^-$ at precisely the value (0.69 eV) required to form the molecular ion. The ethyl radical in this case must, therefore, arise from decomposition of a metastable ion. The effect of electron-withdrawing substituents on the electron energy required for production of (M – Et)$^-$ is both small and in the direction expected for pairing of the incipient nucleophilic oxygen radical with the unpaired phenyl electron (Scheme 1).
5 CONCLUSIONS AND FUTURE DIRECTIONS

The superior sensitivity and selectivity of ECNIMS for electron-capturing compounds continues to attract a large amount of interest. Compounds that absorb low-energy electrons by resonance processes include chlorinated aromatics, chlorinated aliphatics, nitro compounds, polyaromatic hydrocarbons, and organophosphates. These compounds, which may be toxic and of public health concern, are often present in trace amounts. The development of a simple, sensitive, and reliable analytical system for their detection is a compelling goal. Despite the advantages of ECNIMS, there is a basic weakness in the method, which is its unreliability for quantifying small amounts of chemicals. The EMMS system has the potential to remedy this problem because of the elimination of the troublesome reagent gas from the ion source. Data gathered over the past few years indicate that reproducibility of analytical results from this system is better than it is with standard ECNIMS methods. Electron monochromators have been adapted to quadrupole and sector instruments with excellent results and a new source design has led to improved sensitivity over an earlier prototype.

The versatility of this system could be enhanced greatly by interfacing the electron monochromator to an analyzer that would allow simultaneous recording of electron energies and ion masses. The added dimension of analytical information from such a system would provide for more reliable identification of compounds and the three-dimensional print-outs would facilitate interpretation of the data. An electron monochromator interfaced to a time-of-flight analyzer would result in a system that would yield three-dimensional data, as well as open up opportunities for analyzing metastable ions and carrying out “fast” gas chromatography/mass spectrometry for greater efficiency in analyzing trace residues of a large number of compounds in mixtures. Pattern recognition and neural networking could also be used to improve the efficiency of identification of compounds in mixtures. And the analysis of chemicals with functionalities that can be derivatized with electrophores will greatly expand the range of applications of EMMS instruments. In addition to the obvious applications in gas chromatography/mass spectrometry, the electron monochromator could play a crucial role in the analysis of biopolymers. For example, the neutralization of electrosprayed protein and peptide cations and their reionization to negative ions with thermal electrons would be useful in analyzing phosphorylated, sulfated, or otherwise modified peptides. The electron monochromator could also be used to advantage for ionizing post-desorbed neutral molecules in matrix-assisted laser desorption/ionization plumes. Sensitivity enhancement for the detection of oligonucleotides and the identification of peptides with electron-capturing functionalities are among the expected benefits.

Another potential advantage of using EMMS analyzers is that the NIRs can be predicted for unknown compounds within a given class by knowing their virtual orbital energies from high-level Gaussian calculations. These methods have proven reliable for correlating the experimental electron attachment energies of aromatic compounds with their calculated π virtual orbital energies. The resonance attachment energies for electron-capturing aliphatic compounds containing only σ-orbitals should also be predictable. The combination of data from ETS, EMMS and high-level MO calculations will help greatly in providing a better understanding of the mechanisms of ion formation and decomposition. Correlations between the energies of electrons required to produce negative fragment ions from metastable ions[5,122] with data from linked scanning or tandem mass spectrometric analysis will also bring about a better understanding of negative ion gas phase chemistry. The range of applications for elucidating negative ion fragmentations with these instrumental and theoretical methods is extensive and certainly goes well beyond the gas phase. For example, these methods could help in gaining a better understanding of the ionization process in particle beam desorption methods, the effects of solvents on electrochemical and anionic reactions, the photochemical decomposition of exciplexes and the repair mechanism of thymidine dimers by photolyase.

1 Introduction

Mass spectrometers respond to the mass-to-charge, not the mass, of a particle. Thus, the essential first step in any mass spectrometric analysis is to convert the neutral molecules of the analyte to ions or charged particles that can be affected by applied electric or magnetic fields. In EI, the molecules of the analyte must be present in the vapor phase so that they can interact effectively with energetic electrons at reduced pressure. The vacuum is essential so that a reasonable flux of free electrons can be generated and focused into a region of interaction with the analyte molecules. The bombarding electrons are made available, by convention, with 70 eV of kinetic energy. Ionization of the analyte molecule is not necessarily achieved by direct impact by the electron, but rather by interaction of the bombarding electron with the electron cloud of the molecule in a near-miss trajectory. In this way, some of the kinetic energy of the bombarding electron is absorbed by the analyte molecule: a wide range of energies can be transferred to the analyte molecule, but typically an average of 10–12 eV of energy is absorbed by the molecule.

As indicated in Scheme 1, the analyte molecule absorbs approximately 10 eV, which exceeds the ionization potential of the molecule, and thus it expels one of its own electrons to become a molecular ion. Note that the molecular ion thus formed is an odd-electron species.

\[
M + e_{70\text{eV}} \rightarrow M^+ + e_{70\text{eV}} + e_{\text{thermal}}
\]

Scheme 1

The nascent molecular ion formed in the ionization process illustrated in Scheme 1 has considerable excess energy. Typically, the ionization potential of an organic molecule is around 9 eV; thus, the nascent molecular ion formed in the ionization process would in this case have an excess of 1 eV (absorption of 10 eV, minus 9 eV lost during the ionization process). As the molecular ion is in a vacuum, in which the mean free path is on the order of 1 m, it is not likely that it will be able to give up the excess energy through a collision. Thus, the nascent molecular ion will tend to fragment chemical bonds in an effort to give up the excess energy. The bonds that are broken during the fragmentation process are not necessarily the weakest bonds in the molecule, but rather those bonds that lead to the production of a more stable ion (perhaps

Electron ionization (EI) is the basis for one of the most effective mass spectrometric means for identification of a given organic compound. The identification is based on an indication of the molecular weight (MW) coupled with a fragmentation pattern that serves as a chemical fingerprint for the compound. Of the many ionization techniques available in mass spectrometry, EI is one of the most harsh in terms of promoting fragmentation of the molecular ion. The analyst can take advantage of this extensive fragmentation by using some of the fundamental principles of organic mechanistic chemistry and physical chemistry for the purposes of rationalizing the fragmentation pathways that characterize various structural features in an organic molecule. Four basic mechanisms of fragmentation are considered in this chapter; most of them operate on an odd-electron ion, although some pathways will be applicable to even-electron ions as well. The multiplicity of peaks that represent a given ion allows one to estimate the elemental composition of an ion. This information on composition, coupled with a rationalization of a given fragmentation pathway, often enables the structure of a given organic compound to be deduced.\(^{(1-3)}\)

1 INTRODUCTION
an even-electron ion and a reasonably stable radical species) as described in greater detail in a later section.

2 GENERAL APPEARANCE OF THE DATA

The mass spectrum is a data record of the abundance of various ions in the mass spectrometer as a function of their mass-to-charge value. These data are generally available in graphical form such as the bar graph shown in Figure 1. By convention, the ordinate at the left represents the relative intensity of the peaks in the mass spectrum; the peak representing the most abundant ion in the mass spectrum is called the base peak and is assigned a value of 100%. The ordinate on the right-hand side of the bar graph indicates the percentage of total ionization; that is, the abundance of any given ion relative to the sum of the abundances of all the ions. The abscissa is the value of the mass-to-charge on the ion as represented by the symbol \( m/z \) where \( m \) represents the mass of the particle in daltons and \( z \) represents the number of charges on the ion.

The mass of an ion is given in daltons where a dalton is equal to one-twelfth the mass of \( ^{12}\text{C} \). An atomic mass unit is represented by the symbol “u”; this is the same as a dalton (symbol Da). The symbol “amu” is no longer used as, prior to 1961, amu was used by chemists to represent dalton (symbol Da). The symbol \( u \) is now recommended by IUPAC as the unified atomic mass unit and is assigned the value of one-sixteenth the mass of \( ^{16}\text{O} \). The symbol \( u \) is now recommended by IUPAC as the unified atomic mass unit and is assigned the value of one-sixteenth the mass of \( ^{16}\text{O} \).

The chemical fingerprint of 4-decanone is manifest in the mass spectrum shown in Figure 1. The peak at \( m/z \) 156 represents the molecular ion; note that it occurs at an even value of mass-to-charge. The peak at \( m/z \) 43 is the base peak in this mass spectrum. Note that most of the fragment ion peaks occur at an odd value of \( m/z \), namely, \( m/z \) 113, \( m/z \) 99, \( m/z \) 71, \( m/z \) 43, \( m/z \) 41, \( m/z \) 39, \( m/z \) 29, and \( m/z \) 27. Two of the peaks in the “fragment ion region” occur at an even value of mass-to-charge, namely, \( m/z \) 86 and \( m/z \) 58.

It is important to realize that ions exist within the mass spectrometer itself and that the relative concentration of the ions in the mass spectrometer is indicated by their abundance. Peaks in the mass spectrum represent the ions in the mass spectrometer. The abundances of the ions in the mass spectrometer are represented by the intensities of the corresponding peaks in the mass spectrum. Thus, in the mass spectrum of 4-decanone (Figure 1), the ions of \( m/z \) 43 are the most abundant, as indicated by the peak at \( m/z \) 43 being the most intense peak in the mass spectrum.

The peaks at \( m/z \) 156, \( m/z \) 86, and \( m/z \) 58 represent odd-electron ions. The peaks in the mass spectrum at \( m/z \) 113, \( m/z \) 99, \( m/z \) 43, and \( m/z \) 27 represent even-electron ions, as described in a later section.

3 IMPACT OF STABLE ISOTOPES

To an extent limited by the resolution of the mass spectrometer, mass spectrometry is a technique for determining the mass of isotopes as opposed to the atomic weight of an atom.

The issue of average mass of an element (i.e. atomic weight) versus the mass of individual isotopes of an element can be made by examining the mass spectrum of an atom of bromine. As can be found in any elementary text on chemistry, the average atomic weight of bromine is 80 Da. However, as can be seen in the mass spectrum of a bromine atom as shown in Figure 2, there is no peak at \( m/z \) 80 – there is only a peak at \( m/z \) 79, and another at 81. The peak at \( m/z \) 79 represents the nominal mass of bromine, whereas the peak at \( m/z \) 81 represents the isotope peak, which for bromine (and chlorine) occurs two mass units above the nominal mass.

The nominal mass of an element is the mass of the most abundant stable isotope, as rounded to an integer value. The accepted convention in low-resolution EI mass spectrometry is to refer to the nominal mass of an ion regardless of whether it represents a molecular or a fragment ion.

![Figure 1](image1.png) Mass spectrum of 4-decanone.

![Figure 2](image2.png) Mass spectrum of atomic and molecular bromine.
The multiplicity of isotope peaks when more than one atom of a given element is present in an ion is shown by the peaks at m/z 158, 160, and 162 in Figure 2, which represents the mass spectrum of diatomic bromine. The nominal mass of molecular bromine is 158 Da. The peak at m/z 158 represents those molecules of bromine that contain both atoms as the isotope of 79Br. The peak at m/z 160 represents those bromine molecules containing one 79Br isotope combined with one 81Br isotope, the most probable case. The peak at m/z 162 represents those bromine molecules in which both bromine atoms are present as the 81Br isotope, the most probable case. Note that the peak at m/z 158 for the bromine molecule is not the most intense in the isotope cluster, even though it represents the nominal mass of the molecule. This is because of the unusually high abundance of the heavy isotope of Br.

The distinctive multiplicity of isotope peaks for two bromine atoms is present in the mass spectrum of any ion containing these two atoms, as indicated in the spectra shown in Figures 3 and 4. The peak for the nominal mass of the molecular ion has shifted to m/z 172 in Figure 3, a shift of 14 Da representing the mass of a methylene unit (a carbon and two hydrogens). The multiplicity of the peaks at m/z 172, 174, and 176 are again in the ratio of 1:2:1 as they were in Figure 2 because these isotope peaks represent the presence of two bromine atoms.

The mass spectrum of 5,6-dibromo-8-hydroxyquinoline is presented in Figure 4, which shows a peak at m/z 301 for the nominal molecular ion. Again, the distinctive multiplicity of isotope peaks for two bromines is apparent with the peaks at m/z 301, 303, and 305 (as well as at m/z 273, 275, and 277) present in the ratio of 1:2:1.

The impact of the natural abundance of stable isotopes on the appearance of the mass spectral data has been introduced with bromine, an element that has the most abundant stable isotopes of those encountered in organic mass spectrometry. The impact of most of the other elements is much more subtle, but quite important from the standpoint of interpretation. The appearance of carbon can be noted in Figure 3 by the peaks at m/z 173, 175, and 177. The appearance of isotope peaks for carbon are much more apparent in Figure 4 where now the appearance of peaks at m/z 302, 304, and 306 are much more apparent. Note that the isotope peaks for carbon, which are due to the presence of 13C, occur at one mass unit higher than the nominal mass of carbon (12C), whereas for bromine the isotope peak occurred at two mass units above the nominal mass of bromine. Thus, bromine is called an “X + 2” element, where X refers to the nominal mass of the element and 2 refers to the number of mass units above the nominal mass that corresponds to the mass of the isotope. Therefore, carbon is an “X + 1” element because the isotope occurs one mass unit above the nominal mass.

The importance of isotope peaks in the interpretation of mass spectral data is that they provide limits to the elemental composition that should be considered for a given ion. The natural abundance of 13C in 12C is 1.1%. Thus, one can correlate the intensity of the peak at X + 1 with the number of carbon atoms present in the ion. For example, in Figure 3 the peak at m/z 173 is 1.1% of that at m/z 172, and that at m/z 175 is 1.1% of that at m/z 174, etc. In Figure 4, the intensity of the peak at m/z 302 is 9.9% of that at m/z 301, and that at m/z 304 is 9.9% of that at m/z 303, etc. The intensity of the isotope peaks at X + 1 in Figure 4 are more intense than those in Figure 3 because there are nine carbon atoms in dibromomethane and, thus, the probability of having at least one 13C present in a molecule of dibromo-hydroxyquinoline is nine times greater than that in a molecule of dibromohydroxyquinoline, as illustrated in Figure 4 compared to Figure 3. That is to say, in a molecule of dibromohydroxyquinoline, the probability of having one 13C present in the molecule is equal to 9 times 1.1% = 9.9%.

The natural abundances of stable isotopes of other elements that may be present in a given ion are listed in Table 1. The abundances of these stable isotopes at X + 1 and X + 2 are additive, and thus the contributions from 15N and 13C and 17O all occur in the same X + 1 peak in the mass spectrum of a given molecule. However,

as Table 1 shows, the contributions from ¹⁵N and ¹⁷O to X + 1 are substantially less than the contribution of ¹³C at X + 1, thus, the intensity most often observed at X + 1 will be due in large measure to carbon.

Some interesting and characteristic features of organic mass spectrometry can be noted from a cursory examination of the data in Table 1. Note that for all of the elements commonly encountered in organic mass spectrometry, the lightest isotope is always the most abundant. This feature is barely achieved by bromine for which the abundance of the lighter isotope is 50.5%. As indicated in the previous paragraphs, the natural abundance of ¹³C is 1.1%, leaving 98.9% of the atoms present as ¹²C. Whereas this number may seem small, compare it with the natural abundance of deuterium in nature, which is about one part in 10,000. Thus, even though carbon and hydrogen are present in large quantities in most organic molecules, the contribution from carbon to the stable isotope abundance is about two orders of magnitude greater than that from hydrogen. Note also in Table 1 that some elements have no stable isotopes, such as fluorine and iodine.

4 STRATEGY FOR DATA INTERPRETATION

Before any mass spectral data are interpreted in great detail, it is worthwhile determining whether the general quality of the data warrants a detailed investigation. For example, one should examine the data to be certain no artifactual peaks are present or that there are no gross errors in the mass scale calibration, or that there are no peaks that might represent superimposed mass spectra. A detailed examination of the mass spectra will give major consideration to at least four major classes of fragmentation that are described in the next sections.

In general, there are two major reasons for a detailed interpretation of the mass spectra: (a) to predict the likely appearance of peaks at given m/z values should the putative structure be present in the sample, or (b) to use the mass spectral information as a justification for the presence of a given structure in the sample. Either one of these reasons for interpreting the data rely heavily on the general appearance of the mass spectrum and on the mechanistic fragmentation processes described in the following sections. These are the language and nomenclature of mass spectrometry.

5 GENERAL FEATURES OF MASS SPECTRAL DATA

The relative abundance of the molecular ion in the mass spectrum can give a clue as to the type of compound that is undergoing analysis. Because the molecular ion of the compound is the mother of all other ions in the mass spectrum, its relative stability or its resistance to fragmentation suggests some features about its structural makeup. For example, a polyaromatic hydrocarbon resists fragmentation because, in general, more than two bonds must be broken to generate any fragment ions. Thus, the molecular ion peak in the mass spectrum of a polyaromatic hydrocarbon might represent a third or more of all the ion current represented by all the ions in the complete mass spectrum. This kind of information is borne out in Table 2 which shows an approximate relationship between the structure of the analyte and the...
fraction of the total ion current in the mass spectrum that represents the molecular ion. For most of the compounds analyzed by mass spectrometry, only about 1% of the molecular ions will survive and be detected as such. Or, said differently, 99% of the molecular ions will decompose into fragment ions that will be represented by fragment ion peaks in the mass spectrum. In spite of the fact that 1% of the total ion current would seem to be a low number, such a molecular ion would generate a readily distinguishable peak in the mass spectrum. The compounds that create problems for the analyst when determining the identity of an unknown are the classes of compounds typically generate a molecular ion that represents less than 0.1% of the total ion current. Alcohols are an infamous class of compounds from this point of view, in that they do not dependably provide a discernible peak in the mass spectrum that represents the molecular ion.

The nitrogen rule is a very important concept that is helpful in the interpretation of mass spectral data. The nitrogen rule states that any molecule containing carbon, hydrogen, oxygen, halogens, phosphorus, and an odd number of nitrogens will have an odd MW. Such a molecule containing all said elements, but with an even number of nitrogens (including zero) will have an even MW. This is easily demonstrated by simply considering the MW of methane (16 Da) and ammonia (17 Da). A corollary to the nitrogen rule is that any fragment ion that retains an even number of nitrogens will occur at an odd value of mass-to-charge ratio, whereas a fragment ion retaining an odd number of nitrogens will occur at an even value of mass-to-charge ratio, providing that said fragment ions are even-electron species (i.e. that they were formed by expelling a radical from an odd-electron precursor ion).

The fragmentation pattern present in a mass spectrum is established by the molecular ion and certain other fragment ions undergoing a fragmentation process in which logical groups of atoms are lost as a radical or a neutral molecular species. The number of atoms expelled in the fragmentation process must be reasonably consistent with valence considerations of the elements involved. For example, one would not expect a fragmentation process to proceed with the expulsion of a carbon atom or the loss of 12 Da from a given ion. Similarly, one would not expect the loss of 14 Da from a given precursor ion, which would suggest the loss of a nitrogen atom or the loss of a methylene group. This is because neither of these species is sufficiently stable to warrant serious consideration as a decomposition product. Similarly, the loss of 5 Da would also not be expected, as this would suggest the loss of five hydrogens. In summary, one would not expect a molecular ion to lose a group of atoms whose sum would correspond to more than three but less than 15 Da. However, losses of 1, 2 (for H2), 15, 29, or 31 Da would be considered reasonable losses as these could easily correspond to *H, H2, *CH3, *C2H5, or *OCH3, respectively.

6 CURSORY PRELIMINARY EXAMINATION OF MASS SPECTRAL DATA

A careful preliminary examination of the mass spectra may save the considerable frustration that might derive from attempts to interpret poorly calibrated or contaminated mass spectral data. The first major objective in interpreting a mass spectrum is to select a peak in the mass spectrum as a candidate for the molecular ion peak. In the circumstance where it is known that the analyte of interest contains an odd number of nitrogens, and the mass spectrum indicates a peak at highest mass that occurs at an even value of mass-to-charge, it should be suspected that something is wrong. Either the wrong sample has been analyzed, namely one containing a compound that contains an even number of nitrogens and thus would have an even MW, or the m/z scale has not been properly calibrated on the mass spectrometer. This is an example of the case in which the nitrogen rule helps to determine the possibility of bad mass spectral data.

The second step in the general scheme of data interpretation is to test the validity of a candidate molecular ion by determining whether it undergoes reasonable losses in a fragmentation process. If a fragment ion peak is found in the mass spectrum that indicates the candidate molecular ion loses 15 Da, you will have some confidence in the selection of the molecular ion because the loss of 15 Da is a reasonable loss. However, a peak 13 mass units below the peak of the candidate molecular ion should give reason for great concern as 13 Da is not a reasonable loss. This observation casts doubt on the selection of a correct peak for the molecular ion or suggests a contaminated mass spectrum in which the peak 13 mass units below the putative molecular ion represents an impurity.

With the advent of the combined use of gas chromatography and mass spectrometry, the likelihood of obtaining a contaminated mass spectrum or one that consists of the superimposed mass spectra of two or more compounds is relatively low. Such mixed spectra can be obtained, of course, from the mass spectrum of unresolved compounds or one represented by a shoulder of a contaminant peak in the chromatogram. It is also possible that the column bleed from the gas chromatograph could contaminate the mass spectrum; however, the column bleed will be constant and it can be subtracted from the mass spectrum and/or easily recognized and ignored, as shown in the following examples.
Figure 5 Abbreviated mass spectra of unknown compounds.

Now consider the mass spectra in Figure 5 from the point of view of making a preliminary examination of the data. In this cursory examination, assess which peak would represent the molecular ion, whether any suspicious peaks are present in the mass spectrum, and which peaks might be due to contaminants, etc. It would be helpful to do this as an exercise against which to compare the following commentary on each of the mass spectra, to help recognize certain details.

In Figure 5(a) the peak at $m/z$ 412 is a good candidate for the molecular ion as it is consistent with the nitrogen rule for a compound containing no nitrogens, i.e. the peak at $m/z$ 412 occurs at an even value. This candidate peak at $m/z$ 412 is corroborated as a molecular ion peak by the presence of the peak at $m/z$ 397, which could represent a fragment ion formed by the expulsion of a methyl radical, a reasonable loss. Furthermore, the peak at $m/z$ 394 occurs 18 u lower than the peak at $m/z$ 412 and represents the reasonable loss of water from the molecular ion. The peak at $m/z$ 281 is likely to be background arising from column bleed from a siloxane column.

In Figure 5(b) the peak at $m/z$ 227 is a candidate for a molecular ion peak in that it is a peak at highest $m/z$ and, if it does indeed represent a molecular ion, it would represent a compound containing an odd number of nitrogens. The candidacy of the peak at $m/z$ 227 as a molecular ion peak is strengthened by observing a peak at $m/z$ 212 which could represent a fragment ion formed by the ion of $m/z$ 227 losing a methyl group, a reasonable loss. The peak at $m/z$ 198 also represents a reasonable loss from the candidate molecular ion at $m/z$ 227; this would correspond to the loss of 29 Da as an ethyl radical. The peak at $m/z$ 149 could be a part of the mass spectrum which has a molecular ion peak at
m/z 227, although seeing a peak at m/z 149 often suggests contamination of the sample with phthalates, a ubiquitous contaminant in most organic samples these days. The peak at m/z 126 also could be related to the compound of MW 227 Da in that it occurs at an even mass unit, which would suggest a fragment ion retaining the nitrogen.

In Figure 5(c) there is a suspicious peak at m/z 223; the strange feature is that this peak has no isotope peak at m/z 224. As all other peak clusters represented in this brief spectrum do show isotope peaks, it is likely that the peak at m/z 223 represents a noise spike in the particular spectrum and should be discounted unless it occurs in consecutive mass spectra. In any case, some explanation should be made for the fact that it does not have an isotope peak, and until such a reasonable explanation can be made, it should be ignored. Discounting the peak at m/z 223, the next peak of highest mass is at m/z 210, which would be a good candidate for the molecular ion of a compound containing no nitrogen. The suggestion that m/z 210 is a molecular ion peak is strengthened by observing a peak at m/z 195 which would correspond to an ion resulting from the loss of a methyl group from the compound. The peak at m/z 181 also strengthens the candidacy of the peak at m/z 210 as being a molecular ion in that the peak at m/z 181 probably represents the loss of an ethyl radical from the unknown compound.

Figure 5(d) contains peaks at m/z 207 and 281 that are in the expected ratio of 3:1 as would be present in the column bleed background from a siloxane stationary phase in GC/MS (gas chromatography/mass spectrometry) applications. Ignoring these peaks as background gives the same mass spectrum as occurs in unknown spectrum of Figure 5(c).

In Figure 5(e) the peak at highest mass is at m/z 207. Again, this peak is probably due to column bleed background, a feature that would be corroborated if it were possible to see whether there is a peak at m/z 281. In the meantime, the peak at m/z 207 can be ignored, and thus the peak at m/z 186 would be considered a candidate for the molecular ion peak for a species containing no nitrogens. The peaks at m/z 157 and 155 would correspond to the losses of 29 and 31 Da, respectively, which corroborate the candidacy of the peak at m/z 186 as a molecular ion peak. Other peaks continuing down the spectrum occurring at odd mass are consistent with the nitrogen rule except for the peak at m/z 74. This occurs at even m/z thereby suggesting an odd-electron ion which could either be due to a contaminant in the sample or, if proved to be a fragment ion, would suggest a rearrangement of the molecular ion of 186 Da. In fact, the peak at m/z 74 is taken to be a strong indication of the presence of the methyl ester of a fatty acid, the peak at m/z 74 being due to rearrangement about the carbomethoxyl group involving shift of a γ hydrogen with β-cleavage.

Figure 5(f) shows a peak at m/z 185 at high mass with another peak at m/z 180. The difference in mass between 185 and 180 is good reason to be suspicious, as such an increment does not correspond to a reasonable loss. Thus, the peak at m/z 185 does not represent the molecular ion of the same molecule that would have a fragment ion at m/z 180. This observation suggests that this unknown spectrum is that of a mixture of compounds with the peak at m/z 185 representing one compound and the peak at m/z 180 representing an ion of yet another compound. The peak at m/z 165 would appear to be related to the latter compound in that it probably corresponds to the loss of a methyl group from the compound of m/z 180. In any case, some effort should go into an assessment of the analytical procedure before much effort is put into interpreting the complete mass spectrum, as apparently some mixture of spectra is present.

Figure 5(g) has a peak at m/z 190 that would be a reasonable candidate for the molecular ion peak. It occurs at an even value of m/z suggesting the possibility of no nitrogen. Further, its candidacy as a molecular ion peak is corroborated by the presence of a peak at m/z 175, corresponding to the loss of a methyl group, which is a reasonable loss. The peak at m/z 150 is suspicious in that it has no accompanying isotope peak at m/z 151; some verification that this is a legitimate peak and not a noise spike should be pursued before much effort goes into interpretation of the whole spectrum. The peak at m/z 132 could be a molecular ion of a contaminant that contains no nitrogen or it could be a rearrangement fragment ion of the species of m/z 190, although the elimination of 58 Da is somewhat unusual. The peak at m/z 119 could be a fragment ion of the species of m/z 190 in that the peak at m/z 119 occurs at odd mass and is thereby consistent with the nitrogen rule.

In Figure 5(h) the peak at highest mass at m/z 220 is a candidate for the molecular ion peak of a species containing no nitrogen; this is corroborated by the peak at m/z 285 which would correspond to the loss of a methyl group, a reasonable loss of 15 Da. The next cluster of peaks is interesting in that it has the multiplicity of isotope peaks expected for an ion of nominal mass 189 containing two bromines. If this is true, the spectrum is indeed suspect as this observation would indicate the presence of at least two compounds, one containing bromine and one not containing bromine, the latter probably of MW 220 Da. The basis for this realization is that the peak at m/z 189 probably represents a fragment ion of a compound containing no nitrogen; however, it could be the molecular ion of a compound containing an odd number of nitrogens and two bromines, but is surely not related to the species at m/z 220 which does
not contain bromine. Thus, before any further time is
invested in the interpretation of these data, it is important
to determine whether this spectrum had been obtained
under conditions where a substantial impurity was present
or whether it had been obtained by GC/MS of species
that were unresolved from one another.

7 DETAILED EXAMINATION/
RATIONALIZATION OF
FRAGMENTATION

There are two general reasons for a detailed investigation
of the fragmentation processes of molecular ions. One
general use is to anticipate or predict the ways in which
a given known compound is likely to fragment; for this
purpose, try to anticipate peaks in the mass spectrum by
which to recognize the presence of said compound in the
sample. The other general use of fragmentation schemes
is to interpret an unknown mass spectrum for purposes
of deducing the structure of the compound present in the
sample. The latter is much more difficult than the former,
but both rely heavily on the use of the fragmentation
schemes outlined below as these are the language of mass
spectrometrists in describing structure elucidation.

As the molecular ion is the precursor of most of
the fragment ions observed in the mass spectrum, some
consideration should be given to the general form most
often encountered for the molecular ion for certain
classes of compounds. As described at the beginning
of this article, the molecular ion is formed by expulsion
of an electron from the neutral molecule to form an
odd-electron molecular ion. An important question to
contemplate is: which electron is expelled from the
molecule?

For molecules containing a heteroatom (i.e. an atom
other than a carbon or a hydrogen), one of the nonbonding
electrons is most likely to be expelled in formation of the
odd-electron molecular ion. The reason for this is that it
is easier to remove an electron from a nonbonding orbital
than it is from a σ-bonding orbital. In a hydrocarbon
(namely a compound in which there is no heteroatom),
the only choice is to remove an electron from a σ-bond
unless there is a site of unsaturation, in which case it
is likely that the electron would be removed from a π-
orbital). In principle, any of the electrons in a molecule
is available for expulsion in formation of the molecular
ion. However, from an energetic point of view it requires
less energy to expel the electron having the least binding
energy, and thus most of the electrons that are lost in
a molecule containing a heteroatom will come from the
nonbonding orbital.

Because molecules that do contain a heteroatom also
contain many bonds that are made up of σ-bonds, it
is possible to have some of the molecular ions result
from the expulsion of an electron from a sigma bond;
however, these will be in the minority because they are
expensive to produce in that it takes more energy to
remove an electron from a σ-bond than it does from a
nonbonding orbital. An example of ionization by removal
of an electron from a nonbonding orbital is given in
Scheme 2, which shows on the right the molecular ion as
an odd-electron species with the “-” on the oxygen
indicating the site from which the electron was lost.
The same molecule is shown schematically in Scheme 3
which illustrates the process under which a molecular
ion could be produced by σ-bond ionization; note that
the electron deficiency in the molecular ion on the right
of Scheme 3 occurs in the σ-bond between the R and
the first methylene group. Although both molecular ions
produced in Scheme 2 and Scheme 3 would be detected
at the same mass-to-charge value, the one in Scheme 2
having the electron deficiency and the odd electron on the
oxygen is most likely to represent the majority of the cases.
In this article, (as in most mass spectrometry journals and
books), the form of the molecular ion when a heteroatom
is present is written as shown on the right-hand side of
Scheme 2.

The fragmentation process of any ion is driven by
the thermodynamics involved in forming a yet more stable
ion and/or a more stable radical by breaking a chemical
bond. The energetics driving the fragmentation process
can be represented as in Scheme 4 by imagining that the
free energy of ion A plus the free energy of radical B are
less than the free energy associated with the precursor
molecular ion – in which case the process would be driven
by the energy savings in going to the right. If the process
given in Scheme 4 is favorable (i.e. a negative value for
the change in free energy, ΔG), a peak will be seen in the
mass spectrum that represents the ion A⁺. The important
feature to remember is that the bond in the molecular
ion that breaks is not necessarily the weakest bond, but
rather a bond that, when broken, leads to either a much
more stable radical and/or a much more stable ion than
the precursor ion.

\[ \text{M}^{++} \rightarrow \text{A}^+ + \text{B}' \]

Scheme 4
Homolytic cleavage, as introduced schematically in Scheme 5, is frequently used to rationalize specific bond cleavages observed in the fragmentation of molecular ions of molecules containing heteroatoms. As can be seen in Scheme 5, the electron deficiency or radical site exists on the heteroatom, an oxygen in this case, in the molecular ion. In homolytic fission, it is the odd electron that initiates the process. The pairing of electrons leads to a more favorable or stable situation from an energetic point of view. Thus, in homolytic fission, a bond $\alpha$ to the atom adjacent to the atom containing the odd electron is broken in an effort to share yet another single electron with the existing odd electron that occurs on the oxygen in this case. In Scheme 5 a singly barbed arrow indicates the movement of a single electron. Thus, the single barbed arrow $a$ shows the movement of the radical site, whereas the singly barbed arrow $b$ shows the movement of one electron out of a two-electron bond to join the two electrons in a new bond between the oxygen and a carbon in species A$^+$. The species A$^+$ is now an even-electron ion, in this case, an oxonium ion, which is quite stable. The other product of this homolytic cleavage process is a radical species, $^*B$, which has an odd electron. Thus, it may seem that the fragmentation was of no benefit as one of the species still has an odd electron. However, it must be remembered that if enough energy is lost by forming the very stable oxonium ion, then the fragmentation process was beneficial in an overall sense.

The process represented in Scheme 5 is called homolytic fission or cleavage because the bond that undergoes cleavage allows each of the two carbons that were connected by the two electrons to leave the fragmentation process with an electron; in this way, homolysis is an equitable dissociation process. The fragmentation process represented in Scheme 5 is also called $\alpha$-cleavage because it involves cleavage of the bond $\alpha$ to the atom that is adjacent to the atom having the original problem with the odd electron, namely, the oxygen in this case.

Heterolytic cleavage is represented in Scheme 6 where, once again, the site of electron deficiency and an odd electron are on the heteroatom. In heterolytic fission, it is the charge site, rather than the radical site, that initiates the fragmentation process. Heterolytic cleavage differs from homolytic cleavage, in that heterolytic cleavage involves the movement of both electrons from a covalent bond as opposed to the movement of only a single electron from a covalent bond in homolytic fission. As is indicated in Scheme 6, the positive charge on the oxygen induces the movement of both electrons from the adjacent carbon–oxygen bond to move to the oxygen, and away from the carbon atom. This process results in a positive charge developing on the carbon atom as it now has only three devoted electrons around it, rather than the preferred number of four devoted electrons or eight shared electrons; thus, the ethyl ion will be represented by a peak at $m/z$ 29 in the spectrum. In heterolytic fission, the movement of electrons is indicated by a doubly barbed arrow to represent the movement of two electrons, and the charge appears to move from its initial site on the heteroatom.

A rearrangement of a given ion involves the cleavage of at least two bonds, either in a concerted process or in a stepwise process resulting in the elimination of a neutral molecular species. In Scheme 7 the movement of two pairs of electrons is shown in concert, breaking two bonds in a rearrangement to expel an alkene, thereby forming a new even-electron ion of $m/z$ 31 from an even-electron ion of $m/z$ 59. A two-step rearrangement process is shown in Scheme 8 in which the odd-electron molecular ion first undergoes a movement of a hydrogen atom through a six-membered ring to form the distonic ion shown as species B. This then undergoes $\alpha$-cleavage as driven by the radical site on the $\gamma$-carbon to cleave a carbon–carbon bond leading to the formation and expulsion of an alkene, species D. Notice that the rearrangement process here formed a new odd-electron ion, C, from the odd-electron molecular ion.
Cleavage of a σ-bond can occur when ionization of the molecule occurs by removal of an electron from a σ-bond. Whereas σ-bond ionization can occur in any molecule, it is illustrated in Scheme 9 in the form of a hydrocarbon molecular ion (these kinds of molecules have no choice but to be ionized by σ-bond ionization). As can be seen on the molecular ion, the electron that was removed from the molecule was originally part of a pair of electrons between the terminal carbon on the right and the adjacent carbon such that the σ-bond here is now only a one-electron bond; thus, it is weaker than the other bonds in the molecule. If the molecular ion is to fragment, it will surely fragment between carbons 2 and 1, as this is now the weakest bond at this stage because it is only a one-electron bond. If the electronic structure of the molecular ion is as represented in Scheme 9, then cleavage of this carbon–carbon bond will leave the charge on the methyl group (detected to give a peak at m/z 15) and the odd electron will escape as a propyl radical (no signal, as the radical has no charge on it) as shown. If the other electron in the ionized bond had been removed during formation of the molecular ion, and this same bond were to fragment, then the charge would be on a propyl ion (m/z 43), and the odd electron would reside on the methyl group. Because there is nothing to distinguish one σ-bond from another in a hydrocarbon, the ionization of hydrocarbons causes a random distribution of molecular ions, having lost an electron to form a different σ-bond in each of several different forms of the molecular ion. The result is a mass spectrum in which there are peaks every 14 mass units, as shown subsequently in the mass spectrum of a long-chain hydrocarbon.

The mass spectrum of 4-decanone (Figure 1) is worthy of considerable attention as it contains peaks which represent ions formed by each of the four fragmentation processes introduced above. A cursory examination of the peaks in the mass spectrum indicate that, as is consistent with the nitrogen rule, the MW of this non-nitrogen-containing molecule is even with a molecular ion peak shown at m/z 156. The peaks at lower mass-to-charge values mostly occur at odd values with the exception of the peaks at m/z 86 and m/z 58. Peaks occurring at an even value of mass-to-charge for a molecule containing an even number of nitrogens represent odd-electron ions. This is a clue that rearrangements must be possible in this molecule to allow the molecular ion, an odd-electron species, to eliminate a molecular species that, in turn, requires the formation of a different or new odd-electron species. Consecutive stages of two different rearrangements are indicated in Scheme 10 to rationalize the formation of ions represented by the peak at m/z 86 and that at m/z 58. Note in the beginning of Scheme 10 that the odd-electron on the oxygen in the molecular ion initiates the first rearrangement from the longer of the two available γ-hydrogen-containing side chains to eliminate an alkene to generate the species of m/z 86. The distonic ion shown at the upper right in Scheme 10 for the ion of m/z 86 can be rewritten as the radical cation shown in the lower right, which again can initiate, with its radical site, a rearrangement involving the propyl side chain to eliminate an alkene, namely ethylene, to form the distonic odd-electron ion of m/z 58.

Because the rearrangements illustrated in Scheme 10 have been studied so extensively since the early 1960s by F.W. McLafferty, this general rearrangement has affectionately taken on the name of McLafferty rearrangement. However, this overall rearrangement process, which involves γ-hydrogen migration coupled with cleavage of the β-bond, was originally described by Nicholson, who compared photolytic and EI decomposition products of aliphatic ketones.

Recognizing that the ketone contains a heteroatom, namely the oxygen, and that it is the most probable site of

\[
\text{CH}_3\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_3 \rightarrow \text{CH}_3\cdot\text{CH}_2\cdot\text{CH}_2\cdot + \cdot\text{CH}_3 \\
m/z 58 \quad m/z 15
\]

**Scheme 9**

\[
\text{CH}_3\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_3 \rightarrow \text{CH}_3\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_3
\]

**Scheme 10**
ionization, it is expected that homolytic cleavage near the heteroatom would lead to the fragmentation illustrated in Scheme 11. This scheme illustrates that there can be α-cleavage on either side of the carbonyl, leading to the production of an even-electron acylium ion of \( m/z \) 113 in one case and \( m/z \) 71 in the other, both of which are represented by significant peaks in the mass spectrum.

![Scheme 11](image1)

\[
\text{CH}_3(\text{CH}_2)_2\text{C}-(\text{CH}_2)_5\text{CH}_3 + \overset{\cdot}{\text{O}} \rightarrow \text{CH}_3(\text{CH}_2)_2\text{C}-(\text{CH}_2)_5\text{CH}_3^+ \quad m/z \ 156
\]

\[
\text{CH}_3(\text{CH}_2)_2\text{C}-(\text{CH}_2)_5\text{CH}_3 + \overset{\cdot}{\text{O}} \rightarrow \text{CH}_3(\text{CH}_2)_2\text{C}-(\text{CH}_2)_5\text{CH}_3^+ \quad m/z \ 156
\]

\[
\text{CH}_3(\text{CH}_2)_2\text{C}-(\text{CH}_2)_5\text{CH}_3^+ \quad m/z \ 113
\]

\[
\text{CH}_3(\text{CH}_2)_2\text{C}-(\text{CH}_2)_5\text{CH}_3^+ \quad m/z \ 71
\]

\[\text{Scheme 11}\]

Heterolytic fission is also a reasonable possibility and, as shown by the reactions in Scheme 12, the positive charge can induce heterolytic fission on either side of the carbonyl to generate ions of \( m/z \) 43 or \( m/z \) 99, both of which are represented by peaks in the mass spectrum.

Most of the peaks in the mass spectrum of 4-decanone (Figure 1) have been rationalized through the formation of ions involving three of the four fragmentation mechanisms. However, the peak at \( m/z \) 99 has not yet been explained, but α-bond ionization followed by α-bond cleavage is a rational route of fragmentation, as illustrated in Scheme 13.

![Scheme 12](image2)

\[
\text{CH}_3(\text{CH}_2)_2\text{C}-(\text{CH}_2)_5\text{CH}_3 + \overset{\cdot}{\text{O}} \rightarrow \text{CH}_3(\text{CH}_2)_2\text{C}-(\text{CH}_2)_5\text{CH}_3^+ \quad m/z \ 43
\]

\[
\text{CH}_3(\text{CH}_2)_2\text{C}-(\text{CH}_2)_5\text{CH}_3 + \overset{\cdot}{\text{O}} \rightarrow \text{CH}_3(\text{CH}_2)_2\text{C}-(\text{CH}_2)_5\text{CH}_3^+ \quad m/z \ 99
\]

\[\text{Scheme 12}\]

Heterolytic fission is also a reasonable possibility and, as shown by the reactions in Scheme 12, the positive charge can induce heterolytic fission on either side of the carbonyl to generate ions of \( m/z \) 43 or \( m/z \) 99, both of which are represented by peaks in the mass spectrum.

Most of the peaks in the mass spectrum of 4-decanone (Figure 1) have been rationalized through the formation of ions involving three of the four fragmentation mechanisms. However, the peak at \( m/z \) 99 has not yet been explained, but α-bond ionization followed by α-bond cleavage is a rational route of fragmentation, as illustrated in Scheme 13.

8 REPRESENTATIVE MASS SPECTRA OF SELECTED CLASSES OF COMPOUNDS

8.1 Hydrocarbons

The mass spectra of aliphatic hydrocarbons are somewhat monotonous in that they contain a peak every 14 u, as illustrated in Figure 6. The molecular ion peak occurs at an even value of mass-to-charge, whereas all of the major fragment ions occur at an odd value of mass-to-charge, consistent with the nitrogen rule. Because there is no structural feature in the aliphatic carbon backbone that distinguishes one α-bond from another, the molecular ions of these hydrocarbons consist of a random mixture of α-bond-ionized molecular ions, each of which can expel an alkyl radical to give a peak every 14 u. It is important to realize that the peaks occur every 14 u because the molecular ion has the option of expelling homologous alkyl radicals, that is, those differing by 14 Da, depending on which of the many carbon–carbon α-bonds was the site of ionization; the peaks do not represent the loss of 14 Da (which would correspond to a methylene group) from one fragment to the next.

The mass spectra of aromatic hydrocarbons are vastly different in appearance from those of the aliphatic hydrocarbons as can be seen from a comparison between Figure 7 and Figure 6. The molecular ion of a polyaromatic hydrocarbon is quite resistant to fragmentation as more than one bond must be broken to produce a fragment ion. Thus, as indicated in the mass spectrum of anthracene (Figure 7), the molecular ion peak represents nearly half of all the ion current in the mass spectrum.

The mass spectra of other aromatic hydrocarbons, such as the phenyl-containing hydrocarbons, also have characteristic features. For example, if the phenyl ring is connected to the rest of the molecule via an aliphatic carbon chain, the aromatic component is frequently lost.

![Figure 6](image3)

Mass spectrum of hexadecane.
8.2 Alcohols

Aliphatic alcohols pose a serious problem for the mass spectrometrist in that these compounds do not reliably provide a discernible peak for the molecular ion. Thus, the interpretation of the mass spectrum of an alcohol is frequently in jeopardy because there is no indication of the MW of the alcohol. On the other hand, aliphatic alcohols do produce a characteristic peak at \( m/z \) 31, which is a good indicator for the presence of these compounds.

Aliphatic alcohols undergo characteristic fragmentation to generate an ion of \( m/z \) 31 as illustrated in Scheme 15. Note that as usual the radical site is on the heteroatom, namely the oxygen in this case, which promotes homolytic fission to generate the oxonium ion of \( m/z \) 31. Although a peak at \( m/z \) 31 in the mass spectrum of an aliphatic alcohol is rarely the base peak, a peak of any intensity at \( m/z \) 31 is a good indicator of the presence of an alcohol.

The mass spectrum of \( n \)-decanol shows the characteristic features of an aliphatic alcohol (Figure 9). Namely, there is no reliable indication of the molecular ion; note that the MW of \( n \)-decanol is 158 Da, but there is no discernible peak at \( m/z \) 158 in the mass spectrum. The peak at \( m/z \) 31 is certainly not very intense, but its presence is a reliable indicator of an alcohol. The principal peaks in the mass spectrum are those that represent fragmentation of the hydrocarbon backbone of the aliphatic alcohol.

Recognizing that aliphatic alcohols are not well behaved from the standpoint of providing readily interpretable mass spectra, it is frequently desirable to convert the alcohol to another compound which is better behaved during EI mass spectrometry. Conversion of aliphatic alcohols to trimethylsilyl (TMS) ethers, as shown in Scheme 16 for \( n \)-decanol, is frequently used to characterize a given aliphatic alcohol. As will be seen in the following paragraphs, the TMS ether gives peaks in the mass spectrum from which one can determine the MW of the ether, and thus the MW of the parent alcohol.
in addition to learning about other structural features of the alcohol.

Whereas TMS ethers sometimes show a peak in the mass spectrum for the molecular ion, it is clear from examining the mass spectrum of the TMS ether of decanol in Figure 10 that this is not always the case. Nevertheless, the substantial peak at $m/z$ 215 in Figure 10 gives an indirect indication of the MW of the alcohol because the peak at $m/z$ 215 merely represents the loss of a methyl group, which is not part of the parent structure of the alcohol. The trained analyst would know the characteristic fragmentation behavior of the TMS ether derivative in that they readily lose a methyl radical, as shown in Scheme 17 and, with this knowledge, the peak at high mass which occurs at an odd value of mass-to-charge would be recognized as such a fragment ion.

**Scheme 17**

\[
\begin{align*}
\text{CH}_3\text{(CH}_2\text{)}_x\text{CH}_2\text{Si-CH}_3 & \quad \rightarrow \quad \text{CH}_3\text{(CH}_2\text{)}_x\text{CH}_2\text{O-Si-CH}_3 + \text{CH}_3 \\
&m/z 230 & m/z 215
\end{align*}
\]

In summary, by converting aliphatic alcohols to aliphatic ethers, the parent structure of the alcohol is preserved and is represented by high-mass peaks in the mass spectrum of the corresponding ether. The mass spectrum of an ether may show either peaks for both the molecular ion and a fragment ion corresponding to the loss of methyl group, or a peak at high mass corresponding to the loss of the methyl group only; either situation allows the analyst to obtain the critically important information concerning the MW of the alcohol. Note that in the chemical reaction in Scheme 16, the hydrogen on the alcohol group is substituted for a TMS group; the TMS group has a mass of 73 Da, but it replaces a hydrogen which has a mass of 1 Da, thus the shift in mass is $73 - 1 = 72$ Da.

The mass spectra of aromatic alcohols (phenols), are just the opposite in appearance from those of the aliphatic alcohols. Note in the mass spectrum of dichlorophenol in Figure 11, that the molecular ion peak is the base peak.

This indicates that the molecular ion of phenols is very stable, resisting fragmentation. Note also in Figure 11 that the isotope peaks $m/z$ 164 and $m/z$ 166 are in the ratio expected for two chlorine atoms being present in the molecule. This attribute, as well as the fact the phenols are characterized by intense molecular ion peaks, have been used to advantage in environmental chemistry analyses for several years.

### 8.3 Esters of Carboxylic Acids

The methyl esters of long-chain carboxylic acids undergo characteristic rearrangement involving migration of a $\gamma$-hydrogen with $\beta$-cleavage as shown in Scheme 18, which leads to an odd-electron fragment ion of $m/z$ 74. This ion

**Scheme 18**

\[
\begin{align*}
\text{CH}_3\text{(CH}_2\text{)}_x\text{CH}_2\text{OCH}_3 & \quad \rightarrow \quad \text{CH}_3\text{(CH}_2\text{)}_x\text{CH}_2\text{OCH}_3 + \text{H} \\
&m/z 74
\end{align*}
\]
is represented in the mass spectrum of methyl stearate, Figure 12, by the base peak. Note also in Figure 12 that not only does the molecular ion peak occur at an even value of mass-to-charge, namely at $m/z$ 298, thereby representing an odd-electron species, but also the rearrangement fragment ion occurs at an even value of mass-to-charge ($m/z$ 74). The rearrangement ion of $m/z$ 74 is also an odd-electron species as can be seen from the electron accounting shown in Scheme 18. Thus, in accordance with the nitrogen rule, odd-electron ions for compounds containing an even number of nitrogens occur at an even value of mass as verified in Figure 12 and also earlier in Figure 1, which is the mass spectrum of 4-decanone that had two peaks at an even mass-to-charge ratio, namely those at $m/z$ 58 and at $m/z$ 86. The rearrangement ion of $m/z$ 74 for methyl esters may not always be represented by the base peak in the mass spectrum as it is in Figure 12; however, seeing a peak at $m/z$ 74 regardless of its intensity should be suggestive to the analyst of the presence of a methyl ester of a carboxylic acid.

### 8.4 Amines

The fragmentation of an amine is strongly influenced by the "$+$" on the nitrogen in the molecular ion. A cursory inspection of the aliphatic secondary amine in Figure 13 illustrates agreement of the nitrogen rule with the mass spectrum of a compound containing an odd number of nitrogens. Note that the molecular ion peak occurs at an odd mass-to-charge value, namely $m/z$ 101. All the major fragment ion peaks occur at an even value of mass-to-charge value as it will be shown that the ion represented by these peaks retain the nitrogen atom. The fragmentation scheme illustrated in Scheme 19 explains losses that correspond to the loss of an ethyl radical followed by a rearrangement of the even-electron ion of $m/z$ 72 to generate another odd-electron ion of $m/z$ 30. One should not get the impression from Scheme 19 that all the even-electron ions of $m/z$ 72 undergo further rearrangement to eliminate the alkene, because many of the ions of $m/z$ 72 are sufficiently stable to survive long enough to reach the mass analyzer and are detected as a fragment ion having lost only an ethyl radical from the molecular ion.

The peak at $m/z$ 86 is consistent with the loss of a methyl radical, which can be rationalized by homolytic cleavage as illustrated in Scheme 20.

The peak at $m/z$ 44 represents an even-electron fragment ion that can be rationalized by the fragment ion of $m/z$ 86 undergoing a rearrangement, as illustrated in Scheme 21 to eliminate an alkene.

### 9 SUMMARY

This article shows that the fragmentation pattern or the mass spectrum of various classes of compounds contain unique features that help identify the compound type. In addition, four different classes of fragmentation have been presented, and examples shown of the way in which these fragmentation schemes can help rationalize the observed mass spectral data to correlate with or suggest a particular structural feature of the molecule. Consistency of various rules, such as the nitrogen rule, allows one to recognize the integrity of the mass spectral data. The impact of stable isotopes as manifested by the multiplicity of isotope peaks in the mass spectrum allows one to deduce a reasonable estimate of the elemental composition of the ions in the mass spectrum. The elemental composition of the ions as indicated by isotope peaks, and the fragmentation of the molecule after ionization provide a chemical fingerprint of the compound.
that is invaluable from the standpoint of structural elucidation or selective detection of the compound by mass spectrometry.

This review offers an introduction to the principles and generic applications of Fourier transform ion cyclotron resonance/mass spectrometry (FTICR/MS), directed to readers with no prior experience with the technique. The fundamental Fourier transform ion cyclotron resonance (FTICR) phenomenon is explained from a simplified theoretical treatment of ion behavior in idealized magnetic and electric fields. The effects of trapping voltage, trap size and shape, and other nonidealities are then manifested mainly as perturbations that preserve the idealized ion behavior modified by appropriate numerical correction factors. Topics include: effect of ion mass, charge, magnetic field, and trapping voltage on ion cyclotron frequency; excitation and detection of ion cyclotron resonance (ICR) signals; mass calibration; mass resolving power and mass accuracy; upper mass limit(s); dynamic range; detection limit; strategies for mass and energy selection for multiple mass spectroscopy (MS²); ion axialization, cooling, and remeasurement; and means for guiding externally formed ions into the ion trap. The relationship of FTICR/MS to other types of Fourier transform (FT) spectroscopy and to the Paul (quadrupole) ion trap is described. The article concludes with selected applications, an appendix listing accurate fundamental constants needed for ultrahigh-precision analysis, and an annotated list of selected reviews and primary source publications describing various FTICR/MS techniques and applications in fuller detail.

1 INTRODUCTION

FTICR/MS or FTMS is widely practiced, with more than 235 installations worldwide by 1998. In the 24 years since its inception,¹⁻⁴ FTICR/MS has been the sole or principal subject of three books, four journal special issues, and more than 60 review articles (see Further Reading). However, the various prior descriptions and reviews are distributed among dozens of primary publications with different formalism and notation, and those papers are directed mainly at FTICR/MS practitioners. Here, an introduction is given to the principles and generic applications of FTICR/MS, at the minimum depth needed to explain the concepts, directed to those without prior experience in the field.

Fortunately, it turns out that many fundamental aspects of FTICR can be understood from very simple idealized models. First, ion cyclotron frequency, radius, velocity, and energy as a function of ion mass, ion charge, and magnetic field strength follow directly from the motion of an ion in a spatially uniform static magnetic field. Second, ion cyclotron motion may be rendered spatially coherent (and thus observable) by application of a spatially uniform radiofrequency (RF) electric field (excitation) at the same frequency as, i.e. resonant with, the ion cyclotron frequency. The ICR (time-domain) signal results from induction (detection) of an oscillating image charge on two conductive infinitely extended opposed parallel electrodes. A frequency-domain spectrum, convertible to a mass-domain spectrum, is obtained by Fourier transformation of the digitized time-domain ICR signal. Third, confinement of ions by application of a three-dimensional axial quadrupolar direct current (DC) electric field shifts the ion cyclotron frequency, whereas excitation and detection remain essentially linear (i.e. doubling the excitation amplitude doubles the detected ICR signal) but with a reduced proportionality constant. A simple mass calibration rule follows from this treatment. Thus, FTICR/MS may be performed in essentially the same way in ion traps of widely different shape (e.g. cubic, cylindrical). Fourth, collisions broaden the ICR signal in a simple way, and actually make it possible to cool and compress an ion packet for improved detection (and even multiple remeasurement). Fifth, although FTICR/MS has been coupled to virtually every type of ion source, most ion sources work best (or at least most conveniently) outside the magnet. Thus, several methods have been developed to guide externally generated ions into an ion trap inside a high-field magnet. Finally, the above features may be combined in various experimental event sequences (much like pulse sequences in FTNMR (Fourier transform nuclear magnetic resonance) spectroscopy) to perform tandem mass spectrometry (MS/MS, or MS²).

2 ION CYCLOTRON MOTION: ION CYCLOTRON ORBITAL FREQUENCY, RADIUS, VELOCITY, AND ENERGY

An ion moving in the presence of a spatially uniform magnetic field, \( \mathbf{B} = -B_0 \mathbf{k} \) (i.e. the \( z \)-axis is defined as the direction opposite to \( B \)) is subject to a force given (in SI units) by Equation (1),

\[
\text{force} = \text{mass} \times \text{acceleration} = m \frac{dv}{dt} = qv \times \mathbf{B} \tag{1}
\]
in which \( m, q, \) and \( v \) are ionic mass, charge, and velocity, and the vector cross-product term means that the direction of the magnetic component of the Lorentz force is perpendicular to the plane determined by \( v \) and \( B. \) If the ion maintains constant speed (i.e. no collisions), then the magnetic field bends the ion path into a circle of radius \( r \) (Figure 1).

Let \( v_{xy} = \sqrt{v_x^2 + v_y^2} \) denote the ion velocity in the \( xy \) plane (i.e. the plane perpendicular to \( B \)). Because angular acceleration, \( \frac{\text{d}v}{\text{d}t} = \frac{v_{xy}^2}{r} \), Equation (1) then becomes Equation (2)

\[
\frac{mv_{xy}^2}{r} = qv_{xy}B_0
\]

However, the angular velocity \( \omega \) (in radians per second) about the \( z \)-axis is defined by Equation (3),

\[
\omega = \frac{v_{xy}}{r}
\]

so that Equation (2) becomes Equation (4),

\[
mw^2r = qB_0 \omega r
\]

or simply

\[
w_c = \frac{qB_0}{m} \quad \text{(SI units)}
\]

Equation (5) can be expressed as Equation (6),

\[
v_c = \frac{w_c}{2\pi} = \frac{1.535611 \times 10^7 B_0}{m/z}
\]

where \( v_c \) is in hertz, \( B_0 \) in tesla, \( m \) in unified atomic mass units, and \( z \) in multiples of elementary charge.

Equation (5) is the celebrated cyclotron equation, in which the unperturbed ion cyclotron frequency is denoted as \( v_c \). A remarkable feature of Equation (5) is that all ions of a given mass-to-charge ratio \( m/z \), have the same ICR frequency, independent of their velocity. This property makes ICR especially useful for mass spectrometry (MS), because translational energy focusing is not essential for precise determination of \( m/z \).

Several useful conclusions follow directly from Equation (5). First, at a representative static magnetic field value of 7.0 T (at which the corresponding proton nuclear magnetic resonance (NMR) Larmor frequency would be 300 MHz), ICR frequencies for ions formed from typical molecules range from a few kilohertz to a few megahertz (Figure 2), a very convenient range for commercially available electronics.

Rearrangement of Equation (2) yields the ion cyclotron orbital radius of an ion of velocity \( v_{xy} \) (Equation 7),

\[
r = \frac{mv_{xy}}{qB_0} \quad \text{(SI units)}
\]

or

\[
r = \frac{1.036427 \times 10^{-8} (m/z) v_{xy}}{B_0}
\]

In Equation (8) \( r \) is in meters, \( v_{xy} \) in meters per second, \( B_0 \) in tesla, \( m \) in unified atomic mass units, and \( z \) in multiples of elementary charge. For example, the average \( x-y \) translational energy of an ion in equilibrium with its surroundings at a temperature \( T \) (in kelvin), is given by

\[
\frac{m(v_{xy}^2)}{2} \approx kT
\]

in which \( k \) is the Boltzmann constant. Solving Equation (9) for \( v_{xy} \), and substituting back into Equation (7),
yields Equation (10),

$$ r = \frac{1}{qB_0} \sqrt{2mkT} \quad \text{(SI units)} \quad (10) $$

which gives

$$ r = \frac{1.336510 \times 10^{-6}}{zB_0} \sqrt{mT} \quad (11) $$

In Equation (11) $r$ is in meters, $B_0$ in tesla, $m$ in unified atomic mass units, $T$ in kelvin, and $z$ in multiples of elementary charge.

It is quickly confirmed that at room temperature, a singly charged ion of $m = 100$ u in a magnetic field of 3 T (i.e. 30000 G) has an ICR orbital radius of ~0.08 mm. At room temperature, a singly charged ion of mass 10000 u has an ICR orbital radius of only ~0.8 mm, whereas a singly charged ion of 50000 u has an ICR orbital radius of 1 cm. Thus, ions of thermal energy formed from all but the largest molecules are confined by the magnetic field to conveniently small orbital radii for ICR excitation and detection (Figure 3).

Conversely, we can compute the velocity and translational energy of an ion excited (by as yet unspecified means) to a larger-than-thermal orbital radius. Rearrangement of Equation (7) gives Equation (12),

$$ v_{xy} = \frac{qB_0r}{m} \quad \text{(SI units)} \quad (12) $$

which may also be expressed as Equation (13):

$$ v_{xy} = \frac{9.64853 \times 10^7 B_0 r}{m/z} \quad (13) $$

where $v_{xy}$ is in meters per second, $r$ in meters, $B_0$ in tesla, $m$ in unified atomic mass units, and $z$ in multiples of elementary charge.

From Equation (12), a singly charged ion of 100 u excited to an ICR orbital radius of 1 cm in a magnetic field of 3T has a translational velocity $v_{xy}$ of $2.97 \times 10^4$ m s$^{-1}$, corresponding to a translational energy of 434 eV (Equations 14 and 15):

$$ \text{kinetic energy} = \frac{mv_{xy}^2}{2} = \frac{q^2 B_0^2 r^2}{2m} \quad \text{(SI units)} \quad (14) $$

or

$$ \text{kinetic energy} = \frac{4.824 \times 10^7 z^2 B_0^2 r^2}{m} \quad (15) $$

where the kinetic energy is in electron volts, $r$ in meters, $B_0$ in tesla, $m$ in unified atomic mass units, and $z$ in multiples of elementary charge. Thus, ions can be heated to high translational energy even in a relatively small container, and then induced to break into smaller fragments by collision with neutral gas molecules (see below). The dependence of the ion kinetic energy on ICR orbital radius and magnetic field strength is shown in Figure 4.

Finally, it is instructive to note that the excited ion of 100 u of the preceding paragraph travels a distance of about 30 km during a 1 s observation period! That’s basically why ICR offers potentially much higher mass

---

**Figure 3** The ICR orbital radius $r$ (Equation 10), versus ionic mass-to-charge ratio, $m/z$ (in unified atomic mass units per multiple of elementary electronic charge) at each of five representative magnetic field strengths: 1.0, 3.0, 4.7, 7.0, and 9.4 T at 298K. Note that even relatively heavy ions are confined to conveniently small-radius orbits by such magnetic fields.

**Figure 4** Ion translational (kinetic) energy (Equations 14 and 15) as a function of ICR orbital radius, at each of five common magnetic field strengths: 1.0, 3.0, 4.7, 7.0, and 9.4 T, for an ion of $m/z = 100$. Note that ions may be accelerated to relatively high energy ($\approx$1 keV, as in collision-induced dissociation (CID) experiments) while still confined to relatively small (~1 cm) orbital radii (compare with Figure 3).
resolution than even a several-meter long magnetic-sector beam instrument.

3 EXCITATION AND DETECTION OF AN ION CYCLOTRON RESONANCE SIGNAL

3.1 Azimuthal Dipolar Single-frequency Excitation

Ion cyclotron motion is not by itself useful. Virtually all applications are therefore based on excitation produced by applying a spatially uniform electric field oscillating (or rotating) at or near the cyclotron frequency of ions of a particular m/z value. Excitation is used in three ways in FTICR/MS (Figure 5): (a) to accelerate ions coherently to a larger (and thus detectable) orbital radius; (b) to increase ion kinetic energy above the threshold for ion dissociation and/or ion–molecule reaction; and (c) to accelerate ions to a cyclotron radius larger than the radius of the ion trap (see below), so that ions are removed, i.e. ejected, from the instrument.

Next let us apply an azimuthal (i.e. in a plane perpendicular to \( \mathbf{B} \)) spatially uniform electric field \( \mathbf{E}(t) \), oscillating sinusoidally with time along the ±y direction:

\[
\mathbf{E}(t) = E_0 \cos wt \mathbf{j}
\]  
(16)

In Equation (16) and below, \( i \) and \( j \) denote unit vectors along the x- and y-axes. For now, we shall suppose that \( E_0 \) is generated by applying \(+V_0\) and \(-V_0\) volts to two opposed infinitely extended parallel conductive flat plates separated by a distance \( d \) (meters), so that Equation (17)

\[
E_0 = \frac{2V_0}{d} = \frac{V_{pp}}{d}
\]  
(17)
in which \( V_{pp} \) is the peak-to-peak voltage difference between the two plates (Figure 6).

This linearly-polarized electric field may be analyzed into two counter-rotating components, \( \mathbf{E}_L(t) \) and \( \mathbf{E}_R(t) \) (Equation 18).

\[
\mathbf{E}(t) = \mathbf{E}_L(t) + \mathbf{E}_R(t)
\]  
(18)
in which the right-hand terms are given by Equations (19) and (20):

\[
\mathbf{E}_R(t) = \frac{E_0}{2} \cos wt \mathbf{j} + \frac{E_0}{2} \sin wt \mathbf{i}
\]  
(19)
\[
\mathbf{E}_L(t) = \frac{E_0}{2} \cos wt \mathbf{j} - \frac{E_0}{2} \sin wt \mathbf{i}
\]  
(20)

The RF electric field component \( \mathbf{E}_R(t) \), rotating in the same sense (namely, counterclockwise in the xy-plane) and at the same frequency (i.e. in resonance with) the ion of interest pushes that ion continuously forward in its orbit, as shown in the top diagram of Figure 7. The electric field component \( \mathbf{E}_L(t) \), rotating in the opposite sense as the ion, is off-resonance by \( 2w \) and has virtually no significant net effect after several cycles of the excitation frequency.

An ion absorbs power, \( A(t) \), according to the dot product (Equation 21):

\[
A(t) = \text{force} \times \text{velocity} = q \mathbf{E}(t) \times \mathbf{v}_{xy}
\]  
(21)

Figure 6 Excitation voltage difference and detection induced charge difference in FTICR/MS, demonstrated for two infinitely extended parallel flat electrodes located at \( y = \pm d/2 \) m away from the z-axis. If a potential \( V_0 = V_{pp}/2 \) is applied to the upper electrode and \(-V_0\) to the lower electrode, the potential, \( V(y) \), anywhere between the electrodes is \( 2V_0y/d \). If a point charge \( q \) is located between the same electrodes (in the absence of any applied voltage), then the difference, \( \Delta Q(y) \), between the charge induced on the upper and lower electrodes is \(-2qy/d\). It turns out that the relationship, \( \Delta Q/q = -V/V_0 \), is true (by the principle of reciprocity, also known as Earnshaw’s theorem) for opposed electrodes of arbitrary shape.
For a positive (or negative) ion (initially at rest) subjected to oscillating resonant excitation (Equations 16 and 17) for a period $T_{\text{excite}}$, it is straightforward to show from Equation (21) that the postexcitation ion cyclotron radius $r$ is given by Equations (22) and (23):\(^{(7,8)}\)

$$r = \frac{E_0 T_{\text{excite}}}{2B_0} \quad (22)$$

or

$$r = \frac{V_{p-p} T_{\text{excite}}}{2dB_0} \quad (\text{SI units}) \quad (23)$$

A particularly delightful feature of Equation (22) is that the postexcitation ion cyclotron orbital radius is independent of $m/z$! Thus, all ions of a given $m/z$ range can be excited to the same ICR orbital radius, by application of an RF electric field whose magnitude is constant with frequency – i.e. no mass discrimination results from excitation, in the limit of perfectly spatially uniform RF electric excitation field. For example, an ion of arbitrary $m/z$ in a magnetic field of 7.0 T can be excited to a radius of 0.72 cm in 1.0 ms by a constant RF resonant oscillating voltage of $\pm 1 \text{ V} \quad (2V_{p-p})$ applied to infinitely extended parallel flat electrodes 2 cm apart. Thus, ions can be excited to a detectably useful ICR orbital radius (i.e. to a cyclotron radius large compared to the ion initial room-temperature thermal cyclotron radius) by a relatively small RF voltage.

From Equations (22) and (23), and remembering that $w_c = qB_0/m$, the ion kinetic energy immediately following azimuthal dipolar resonant excitation for a period $T_{\text{excite}}$, is given by Equations (24) and (25):

$$\text{kinetic energy}_{\text{postexcite}} = \frac{m w_c^2 r^2}{2} = \frac{q^2 E_0^2 (T_{\text{excite}})^2}{8m}$$

$$= \frac{q^2 V_{p-p}^2 (T_{\text{excite}})^2}{8d^2 m} \quad (24)$$

$$\text{kinetic energy}_{\text{postexcite}} = \frac{1.20607 \times 10^7 z^2 V_{p-p}^2 (T_{\text{excite}})^2}{d^2 m} \quad (25)$$

in which the kinetic energy is in electron volts, $V_{p-p}$ is in volts, $T_{\text{excite}}$ is in seconds, $d$ is in meters, $m$ is in unified atomic mass units and $z$ is in multiples of elementary charge. For example, for an ion of 100 u, excited by $\pm 1 \text{ V}$ applied for 1 ms to infinitely extended parallel flat electrodes 2 cm apart, the postexcitation ion kinetic energy is 1.2 keV. Thus, it is relatively easy to generate a high collision energy (see below) in an ion cyclotron. Equations (24) and (25) show that, for a given excitation electric field amplitude and duration, the postexcitation ion kinetic energy is independent of magnetic field strength $B_0$. However, the postexcitation cyclotron radius (Equation 22) varies inversely with $B_0$, so that for a given postexcitation ion cyclotron radius, the postexcitation ion energy increases as $B_0^{\frac{1}{2}}$.\(^{(7)}\) The postexcitation ion kinetic energy as a function of ion mass, is shown in Figure 8, for either fixed postexcitation radius at several different magnetic field values, or fixed excitation amplitude but several different excitation periods.

### 3.2 Azimuthal Dipolar Single-frequency Detection

It is important to recognize that ICR orbital motion does not by itself generate an observable electrical signal (namely, a net difference between the charge induced in two opposed parallel electrodes). At its instant of formation in (or injection into) the ion trap, the phase of each ion’s orbital motion is random – i.e. an ion may start its cyclotron motion at any point around either circle shown in Figure 1. Thus, for an ensemble of ions, any charge induced in either of two opposed detector plates will be balanced, on average, by an equal charge induced by an ion whose phase is 180° different (i.e. an ion located on the far side of the same orbit), so that the net difference in detected charge between the two plates is zero. Moreover, the cyclotron radius of thermal ions is too small to induce a detectable signal, even if all ions of a
Figure 8 Post excitation ion kinetic energy as a function of ion mass. (a) Fixed post excitation cyclotron radius of 1 cm, for each of five magnetic field strengths: 1.0, 3.0, 4.7, 7.0, and 9.4 T. (b) Fixed excitation electric field \( D_{\text{pp}} \) applied between electrodes 2 cm apart, for each of five excitation durations.

The difference \( \Delta Q \) in image charge on two opposed infinitely extended parallel flat conductive plates, induced by an ion of charge \( q \) between the plates, is given by Equation (26) (see Figure 6),

\[
\Delta Q = -2qy/d
\]  

(26)

The ICR signal is proportional to the induced current (Equation 27),

\[
\frac{d\Delta Q}{dr} = -\frac{2q(dy/dr)}{d}
\]

(27)

and is thus independent of magnetic field strength. Moreover, because the ion y-velocity component, \( dy/dt \), increases linearly with ion cyclotron radius (Equation 7), the ICR signal increases linearly with ion cyclotron postexcitation radius. Also, the detected signal increases linearly with the ion charge, so that ICR is increasingly more sensitive for multiply charged ions (as from electrospray ionization (ESI)). Linearity is especially important for two reasons. First, because the ICR signal varies linearly with ion cyclotron postexcitation radius (which in turn depends linearly on the product of the excitation voltage amplitude and the duration), the ICR response at any frequency is proportional to the excitation spectral magnitude at that frequency. (This idea is used in the next section to show how frequency-sweep or off-resonant or stored waveform inverse Fourier transform (SWIFT) excitation works.) Second, a FT of the time-domain ICR response gives the same absorption spectrum that would otherwise have been obtained by measuring power absorption while sweeping infinitely slowly across the \( m/z \) range. In addition, the superposition principle implies that the signals from any number of ions of arbitrary \( m/z \) values simply add at the detector; thus, ions over a wide \( m/z \) range can be detected simultaneously. The previous two statements combine to constitute the multichannel advantage of pulsed excitation followed by Fourier transformation to yield a spectrum of \( N \) data points in \( 1/N \) the time it would take to scan the spectrum one channel at a time. We shall next examine broadband excitation and defer further consideration of the ICR signal until we have discussed the effect of ion-neutral collisions.

3.3 Broadband Excitation

So far, we have examined the response of an ion in a static spatially homogeneous magnetic field, \( B = -B_0 k \), to a single-frequency resonant (at \( w_c \)) oscillating electric field, \( E(t) = E_0 \cos w_c t j \). However, the very act of turning the excitation on and off generates excitation at other frequencies, as shown in Figure 9. For example, the frequency-domain spectrum \( E(\omega) \), of single-frequency excitation at frequency \( w_c \), applied steadily for \( T_{\text{excite}} \)
seconds, is given by Equation (28):\(^{(14)}\)

\[
E(v) = E_0 \frac{\sin(2\pi v T_{\text{excite}})}{2\pi v_c} \tag{28}
\]

Thus, although the applied excitation may be precisely centered at a frequency \(w\), which differs from \(w_c\), turning the excitation voltage on at time zero and off at time \(T_{\text{excite}}\), effectively broadens the spectral range of the excitation (to a bandwidth of \(\sim 1/T_{\text{excite}}\) hertz). The longer the time-domain signal duration, the narrower is its corresponding frequency-domain spectral width. Thus, if an off-resonance excitation at frequency \(v\) is sufficiently brief that \((1/T_{\text{excite}}) \geq 2\pi|v - v_c|\) it can still excite ions of cyclotron frequency \(w_c\). This general result defines the

ultimate precision with which ions can be mass-selected by their ICR frequencies. Fortunately, because ion cyclotron frequencies are so high (typically kilohertz to megahertz), excitation for as short as one second is still exquisitely mass selective (for instance about 10 ppm for ions of \(m/z = 1000\) at \(7.0\) T).

Equation (28) shows that single-frequency excitation of duration \(T_{\text{excite}}\) can excite ions whose ion cyclotron frequencies span a range of \(\sim 0.1/T_{\text{excite}}\) Hz to near-uniform cyclotron radii. (As the ICR signal magnitude is proportional to the postexcitation ICR orbital radius, which is in turn proportional to excitation magnitude, we seek a flat excitation magnitude spectrum in order to produce a mass spectrum whose peak areas accurately reflect the relative abundances of ions of different \(m/z\).) However, Figure 9(a) and 9(b) shows that doubling the excitation frequency-domain bandwidth while maintaining the frequency-domain magnitude requires halving the time-domain excitation duration and doubling the time-domain amplitude. Thus, given that a single-frequency resonant excitation voltage of \(\pm 1\) V (between electrodes about 2 cm apart) is needed to excite ions to a detectable cyclotron radius of 1 cm in 1.4 ms (based on Equation 22), excitation of ions anywhere within a bandwidth \(\sim 1\) MHz to near-uniform cyclotron radii will require single-frequency excitation of \(\sim 0.1\) µs (i.e. about one-tenth of the width of the sinc function of Equation 28), corresponding to \(\sim 10^4\) V (i.e. inconveniently large) RF excitation voltage. Therefore, broadband ion cyclotron excitation is commonly performed by frequency-sweep (i.e. chirp) excitation (Figure 9c),\(^{(1-4,14,15)}\) which achieves excitation of relatively flat magnitude over a broad frequency range by use of relatively low excitation voltage (see section 7).

The disadvantages of chirp excitation are evident in Figure 9(c) – nonuniform excitation amplitude (translating to variation in apparent ion relative abundances) across the spectrum, and limited mass selectivity at the start and end frequencies of the sweep. Fortunately, a very general excitation mode is made possible by the highly linear excitation–response of ICR. The idea is simply to reverse the process, and begin by defining the desired excitation profile in the mass domain, converting it to a frequency-domain excitation spectrum, and then performing an inverse FT to generate the desired time-domain excitation waveform,\(^{(16,17)}\) as shown in Figure 9(d) and 9(e). In this way, one can create mass spectral windows within which none (or all) of the ions are excited or ejected, thereby providing complete broadband mass selectivity for MS/MS or for enhanced dynamic range\(^{(18)}\) by selective ejection of highly abundant ions. SWIFT achieves the flattest and most frequency-selective excitation magnitude spectrum theoretically possible for a given time-domain excitation period. The principles and

\end{figure}
uses for SWIFT excitation (for both Penning (ICR) and Paul (quadrupole)) ion traps have been reviewed.\(^{19}\)

### 3.4 Broadband Detection, Detection Limit

A coherently orbiting ion packet induces a differential current between two opposed detection plates and may be modeled as a current source. The receiver plates and wiring that connect the ion trap to the detection preamplifier have an inherent resistance and capacitance in parallel (see Figure 7).\(^{9,10,12,13}\) Experimentally, at typical ICR frequencies (>10 kHz) the signal-to-noise ratio is independent of cyclotron frequency. However, at sufficiently low frequency (<10 kHz), the signal varies directly with frequency. Therefore, throughout most of the frequency range excited by a broadband chirp or SWIFT waveform in a standard FTICR/MS experiment, the detected signal-to-noise ratio reflects the relative current differential induced on the detection plates. Furthermore, the detection limit (namely, the minimum number of ions that may be detected from an undamped signal in a single 1 s acquisition period to yield a signal-to-noise ratio of 3:1) may be calculated from Equation (29),

\[
N = \frac{CV_{\text{dp-p}}}{qA_1(r)} \quad (29)
\]

in which \(C\) is the capacitance of the detection circuit, \(V_{\text{dp-p}}\) is the peak-to-peak amplitude of the detected voltage (calibrated for a given spectrometer), and \(A_1(r)\) is a coefficient that is approximately proportional to \(r\) and may be determined graphically.\(^{30}\) For example, for typical operating parameters, namely a detection circuit capacitance of 50 pF, \(V_{\text{dp-p}}\) of \(3 \times 10^{-7} V\), and \(A_1(r) = 0.5\) (i.e. the ion is excited to approximately half of its maximal cyclotron radius), an observed signal-to-noise ratio of 3:1 corresponds to a detection limit of about 187 ions.

### 4 ION-NEUTRAL COLLISIONS

For ions of a single \(m/z\) value, the ICR frequency-domain response in the absence of collisions looks just like Equation (28), and is obtained by Fourier transformation of a digitized time-domain signal to give a sinc function spectrum that looks just like Equation (14), except that \(T_{\text{excite}}\) is replaced by the data acquisition period \(T_{\text{acq}}\). The simplest way to treat ion-neutral collisions is to model their effect as a frictional damping force in the overall ion motion:

\[
\text{force} = m \frac{dv}{dt} = qE + qv \times B - f(v) \quad (30)
\]

This model\(^{21,22}\) leads to an exponential damping (Equation 31) of the time-domain ICR signal for \(N_t\) ions of ICR frequency \(v_t\),

\[
s_i(t) \propto N_t \exp \left( -\frac{t}{\tau} \cos(2\pi v_t t) \right) \quad (31)
\]

whose FT yields a Lorentzian frequency-domain magnitude spectrum (Equation 32):

\[
M(w) \propto \frac{\tau}{\sqrt{1 + (w - 2\pi v_t)^2 \tau^2}} \quad (32)
\]

Thus (Figure 10), the FTICR spectral line shape approaches the sinc shape in the limit of zero pressure (i.e. \(\tau \gg T_{\text{acq}}\), so that there are essentially no ion-neutral collisions during data acquisition), and approaches the Lorentzian shape in the high-pressure limit (\(\tau \ll T_{\text{acq}}\)) that the signal has damped nearly to zero during the data acquisition period. These line shapes define mass resolution and mass resolving power, as discussed below. The factor \(\tau\) may be defined as in Equation (33),\(^{22}\)

\[
\frac{1}{\tau} = \frac{m_{\text{neutral}}}{m_{\text{ion}} + m_{\text{neutral}}} v_{\text{collision}} \quad (33)
\]

in which \(v_{\text{collision}}\) is the number of ion–molecule collisions per second. In order to calculate \(v_{\text{collision}}\), one must first determine the rate constant for ion–molecule collisions.

**Figure 10** Simulated time-domain ICR signals (left) and frequency-domain magnitude spectra (right) for: (a) low-pressure, \(\tau \gg T_{\text{acq}}\); (b) intermediate-pressure, \(\tau \approx T_{\text{acq}}\); and (c) high-pressure, \(\tau \ll T_{\text{acq}}\) limits.
At thermal velocity, an ion and a neutral molecule interact through the ion-induced dipole (Langevin) potential (Equations 34 and 35): \[ U(r) = -\frac{\alpha^2 q^2}{8\pi\varepsilon_0 r^2} \quad (\text{SI units}) \] \[ U(r) = -\frac{\alpha^2 q^2}{2a^4} \quad (\text{cgs units}) \]
in which \( q \) is the ion charge, \( \alpha^2 \) is the isotropic polarizability of the neutral, \( r \) is the distance between the two bodies, and the ion is modeled as a point charge. From this interaction potential and the Langevin model the ion–neutral collision rate constant may be calculated (Equations 36 and 37):

\[ k = \frac{\pi\alpha^2 q^2}{6\varepsilon_0\mu} \quad (\text{SI units}) \] \[ k = \frac{4\pi^2\alpha^2 q^2}{\mu} \quad (\text{cgs units}) \]

At this juncture, a note about units is in order. The parameter \( k \) is almost always reported in cgs units. In cgs units, the elementary charge \( q \) is \( 4.8065\times10^{-10} \) statcoulombs (electrostatic units or esu), \( \alpha^2 \) is in cubic centimeters, and \( \mu \) (the reduced mass of the ion and molecule) is in grams. Thus, in order to obtain the collision frequency for one ion, the pressure must be computed in number of molecules per cubic centimeter. For example, suppose that the pressure inside the Penning trap is \( 1 \times 10^{-8} \) torr, corresponding \( PV = nRT \) to a neutral concentration of \( 3.24\times10^8 \) molecules per cubic centimeter at a temperature of 298.15K. For an ion of 100u colliding with nitrogen (N\(_2\)) molecules, the neutral polarizability, \( \alpha^2 = 1.7403\times10^{-24} \text{ cm}^3 \). From these values, Equation (37) yields an ion–neutral collision rate constant, \( k = 6.61\times10^{-10} \text{ cm}^3 \text{ s}^{-1} \). If we now multiply this number by the neutral concentration, we obtain \( v_{\text{collision}} \approx 0.2 \) collisions per second per ion.

Recently, it has been pointed out that the collisional model just described derives from a Langevin (ion–induced dipole) collision model. Although the Langevin model offers a good description for room-temperature ions, a hard-sphere collision model is much more appropriate for the much higher velocities of ions during FTICR data acquisition. Equations (29) and (30) then take the form of Equation (38):

\[ \text{force} = m\frac{dv}{dt} = qE + qv \times B - f v^2 \]

Instead of exponential damping of the ion velocity with time, the ion velocity, \( v(t) \), is now represented by Equation (39),

\[ v(t) = \frac{v_0}{1 + v_0 [(m_{\text{neutral}}/(m_{\text{neutral}} + m_{\text{ion}}))] N \sigma_{\text{hard sphere}} t} \]

in which \( N \) is the neutral number density, \( \sigma_{\text{hard sphere}} \) is the hard-sphere collision cross-section, and \( m_{\text{neutral}} \) and \( m_{\text{ion}} \) are the neutral and ion masses. Although there is no analytical FT of Equation (33), it can be transformed numerically to yield a frequency-domain line shape that has a narrow width at half-maximum peak height, but is very broad at the base. At present, FTICR time-domain signals are typically weighted (windowed, apodized) so as to suppress the broad base of the true hard-sphere line shape; however, the natural line shape may prove useful for future quantitation of ion–neutral collision frequencies (e.g. for comparison to ion mobilities measured in beam instruments).

5 EFFECTS OF AXIAL CONFINEMENT OF IONS IN A TRAP OF FINITE SIZE

Up to now, we have considered only idealized ion behavior in a spatially uniform \( B \) field and an orthogonal spatially uniform oscillating \( E \) field. Here we show how those results are modified by the need to perform the experiment in a cell of finite dimensions. First, a static magnetic field applied along the \( z \) direction effectively confines ions in the \( x \) and \( y \) directions according to the cyclotron motion described above. However, ions are still free to escape along the \( z \) axis (i.e. along or opposed to the magnetic field direction). In order to prevent such escape, it is usual to apply a small (~1 V) electrostatic potential (ideally three-dimensional axial quadrupolar, see below) to each of two end cap electrodes positioned at \( z = \pm a/2 \) from the center of the cell. Second, because the electrodes that generate the electrostatic trapping potential and the excitation (or detection) electric potentials are necessarily finite in size, the resultant electric field is nonlinear (and reduced in magnitude) from that from infinitely extended opposed parallel flat conductive plates. We next show briefly how these two perturbations affect the FTICR experiment.

5.1 Axial Ion Oscillation Due to the \( z \) Component of the Electrostatic Trapping Potential

The optimal one-dimensional potential for axial confinement of ions would be a simple quadratic potential, \( \Phi(z) \propto (z^2/2) \), because the gradient of that potential yields a simple harmonic restoring force, so that ions oscillate sinusoidally back and forth between the end cap electrodes, at a frequency independent of ion \( z \) position. However, in three dimensions, Laplace’s equation,
\[ \nabla^2 \Phi(x, y, z) = 0, \] requires the addition of terms in \( x^2 \) and \( y^2 \). Hans Dehmelt and Wolfgang Paul, in work that laid the basis for their shared Nobel prize in 1989, exploited the experimentally convenient (i.e. cylindrically symmetric) three-dimensional axial quadrupolar electrostatic trapping potential of Equation (40),

\[
\Phi(x, y, z) = V_{\text{trap}} \gamma + \frac{\alpha}{2a^2} (2z^2 - x^2 - y^2) \tag{40}
\]
or Equation (41)

\[
\Phi(r, z) = V_{\text{trap}} \gamma + \frac{\alpha}{2a^2} (2z^2 - r^2) \tag{41}
\]
in which \( r = \sqrt{x^2 + y^2} \) is the radial position of the ion in the \( x-y \) plane, \( a \) is a measure of trap size, and \( \gamma \) and \( \alpha \) are constants that depend on the trap shape.\(^{27}\) The shape of the potential of Equations (40) and (41) is graphically evident from a plot of its isopotential surfaces (Figure 11).

Values of \( \gamma \) and \( \alpha \) for several ICR trap shapes (Figure 12) in common use are shown in Table 1. Methodology for computing \( \gamma \) and \( \alpha \) for orthorhombic, tetragonal, and cylindrical traps of arbitrary aspect ratio is available.\(^{44}\) The dipolar excitation fields for cubic and cylindrical (unit aspect ratio) traps are essentially identical, if the excitation voltage is about 1.4 times higher for the cylindrical trap; similarly, the detected signal from the cylindrical trap is about 0.7 of that for a cubic trap whose corners just touch the inner walls of the comparable cylindrical trap. (We have chosen a cubic trap inscribed (rather than circumscribed) relative to a cylinder, because both traps then each have the largest possible equal diameter, and thus are equally separated from the inner (cylindrical) wall of the enveloping vacuum chamber.) The hyperbolic trap is near-perfect for trapping potential, but is very nonlinear for dipolar excitation. Although capacitive coupling of the three-cylinder open trap improves its dipolar excitation linearity only slightly for ions in the \( z = 0 \) midplane, the capacitively coupled design provides near-linear excitation from one end of the trap to the other, and therefore virtually eliminates \( z \) ejection. Also, although \( \beta_{\text{quad}} \) for the matrix-shimmed trap is not as large as for the cylindrical traps, it closely approximates the ideal \( \beta_{\text{quad}} \) of 8/3 (i.e. the limiting value for an infinitely extended tetragonal trap). The infinity trap improves dipolar excitation, but not (in the absence of an additional switching network) dipolar detection, and requires that quadrupolar excitation be performed with two-plate rather than four-plate excitation.\(^{45}\)

From Equations (40) and (41) it is straightforward to solve the Equation (42) of ion \( z \) motion,

\[
\text{axial force} = m \frac{d^2z}{dt^2} = -q \nabla \Phi(x, y, z) \tag{42}
\]
to obtain an ion \( z \) position that oscillates sinusoidally with time (Equations 43–45)

\[
z(t) = z(0) \cos(2\pi v_z t) \tag{43}
\]
in which

\[
v_z = \frac{1}{2\pi} \sqrt{\frac{2qV_{\text{trap}}}{ma^2}} \quad \text{(SI units)} \tag{44}
\]
or

\[
v_z = 2.21088 \times 10^3 \sqrt{\frac{zV_{\text{trap}}}{ma^2}} \tag{45}
\]

$^a$ Approaches the value of $\beta_{\text{dipolar}}$ for an infinitely long cylindrical trap.

$^b$ Cannot perform traditional four-plate quadrupolar excitation without additional circuitry and switching; however, two-plate quadrupolar excitation may be used instead.$^{(41)}$

$^c$ Three consecutive right circular cylinders, each of unit aspect ratio, capacitively coupled or not. In this case, $a$ refers to the length of the central cylinder.

$^d$ Requires capacitive coupling of the detection electrodes as well as the excitation electrodes.

$^e$ Up to a radius of $a/4$ (i.e. halfway from the trap central axis to the side of the trap).

where $\nu_z$ is in hertz, $V_{\text{trap}}$ in volts, $a$ in meters, $m$ in unified atomic mass units, and $z$ in multiples of elementary charge. For example, for $V_{\text{trap}} = 1$ V in a cubic trap of side length $a = 2.54$ cm, an ion of $m/z = 1000$ will oscillate at a trapping frequency of 4580 Hz.

5.2 Radial Ion Magnetron Rotation Due to Combination of the Magnetic Field and the Radial Component of the Electrostatic Trapping Potential

The DC trapping potential of Equations (40) and (41) also produces a radial force (Equation 46):
radial force \( = qE(r) = \frac{qV_{\text{trap}}\alpha}{a^2} r \) \hspace{1cm} (46)

The radial electric field acting on the ion produces an outward-directed electric force which opposes (and thus has opposite sign with respect to) the inward-directed Lorentz magnetic force from the applied magnetic field. We can now combine Equation (46) with Equation (5) to obtain the equation for ion motion subject to a static \( \mathbf{B} = B_0 \mathbf{k} \) field and a three-dimensional axial quadrupolar electrostatic potential of Equation (41), giving Equation (47):

\[
\text{force} = mw^2 r = qB_0w r - \frac{qV_{\text{trap}}\alpha}{a^2} r \hspace{1cm} (47)
\]

or

\[
w^2 - \frac{qB_0w}{m} + \frac{qV_{\text{trap}}\alpha}{ma^2} = 0 \hspace{1cm} (48)
\]

Note that Equation (48) is quadratic in \( w \), but that \( w \) is independent of \( r \)! That is the great advantage of the three-dimensional axial quadrupolar DC trapping potential – namely, each of the resultant ion motional frequencies (see below) is independent of ion position inside the trap. Solving Equation (48) for \( w \), gives two natural rotational frequencies (in radians per second) in place of the original unperturbed cyclotron frequency that is observed in the absence of DC trapping potential (Equations 49–52):

\[
w_+ = \frac{w_c}{2} + \sqrt{\left( \frac{w_c}{2} \right)^2 - \left( \frac{w_z}{2} \right)^2} \text{ (reduced cyclotron frequency)} \hspace{1cm} (49)
\]

\[
w_- = \frac{w_c}{2} - \sqrt{\left( \frac{w_c}{2} \right)^2 - \left( \frac{w_z}{2} \right)^2} \text{ (magnetron frequency)} \hspace{1cm} (50)
\]

in which

\[
w_z = \sqrt{\frac{2qV_{\text{trap}}\alpha}{ma^2}} \text{ (trapping oscillation frequency, in SI units)} \hspace{1cm} (51)
\]

and

\[
w_c = \frac{qB_0}{m} \text{ (unperturbed cyclotron frequency, in SI units)} \hspace{1cm} (52)
\]

The three natural ion motional modes (cyclotron rotation, magnetron rotation, and trapping oscillation) are shown in Figure 13, and their relative frequencies as a function of ion \( m/z \) and DC trapping potential are shown in Figure 14.\(^{46}\) The magnetron and trapping frequencies are usually much less than the cyclotron frequency, and generally are not detected (except as small sidebands when the ion trap is misaligned with the magnet axis and/or ion motional amplitudes approach the dimensions of the trap).\(^{5,47,48}\)

### 5.3 Mass Calibration

Equation (49) shows that the imposition of a quadrupolar DC trapping potential reduces the ion cyclotron orbital frequency, because the radially outward-directed magnetic field effectively reduces the magnetic field strength. In the absence of electric space charge and trapping potentials, measurement of the frequency of a single ion of known mass would serve to calibrate the magnetic field strength, from which the \( m/z \) values of all other ions in the mass spectrum could be computed from Equation (5). However, the introduction of trapping potential changes the ICR mass–frequency relationship to the form shown in Equation (49), from which Equation (53) can be derived.\(^{49}\) The factors \( A \) and \( B \) are constants obtained by fitting a particular set of ICR mass

**Figure 13** Ion motion in a 2 in cubic Penning trap in a perfectly homogeneous magnetic field of 3 T for an ion of \( m/z \) 2300, for 10 V trapping voltage. The three natural motional frequencies and amplitudes have relative magnitudes given by \( w_+ = 4.25w_c \), \( w_z = 8.5w_c \), \( \rho_+ = 4\rho_c \), \( \rho_- = 8\rho_c \). Note that the field produced by a cubic trap is not perfectly quadrupolar as manifested by the shape of the magnetron orbit (not a perfect circle) in the \( xy \) plane. The magnetic field points in the negative \( z \) direction.
spectral peak frequencies for ions of at least two known m/z values to Equation (53):

\[
\frac{m}{z} = \frac{A}{v_z} + \frac{B}{v_z^2}
\]  

(53)

Strictly speaking, Equations (49–53) should be valid only in the single-ion limit (i.e., no Coulomb interactions between ions). In practice, however, FTICR/MS experiments are usually performed with sufficiently few ions that the space charge perturbation is small; moreover, the perturbation affects both calibrant and analyte ions. This is basically why ICR mass calibration works so well, even when many ions are present. Internal calibration (i.e., calibrant ions are present along with analyte ions in the same sample) typically improves mass accuracy by a factor of at least three compared to external calibration (i.e., calibration is performed on a separate sample from the analyte). External calibration works best when calibrant ions are excited to the same cyclotron radius as analyte ions and when the number of ions in the trap is the same for both experiments.

6 QUADRUPOLAR EXCITATION, AXIALIZATION, AND ION REMEASUREMENT

So far, it has been shown that a three-dimensional axial quadrupolar electrostatic potential (see Figure 11a) is optimal for trapping ions for ICR, and that a one-dimensional linear RF electric potential (see Figure 11c), which produces a spatially uniform RF electric field, is optimal for ICR excitation/detection. We now discuss the purpose of a two-dimensional azimuthal quadrupolar RF potential (see Figure 11b). It can be shown\(^\text{50}\) that such a potential (oscillating at the unperturbed ion cyclotron frequency \(w_c = qB_0/m\)) periodically interconverts magnetron and cyclotron motions. As a matter of fact, it has been shown that such an experiment is formally analogous to resonant excitation in a two-level spin one-half magnetic resonance experiment: conversion from pure magnetron to pure cyclotron motion corresponds to population inversion by a \(\pi\)-pulse.\(^\text{51}\)

In the presence of collisions, the ion magnetron radius increases slowly with time, whereas the ion cyclotron radius decreases rapidly with time. Thus, if the magnetron radius (i.e., the radial position of the center of an ion cyclotron orbit) is converted to the cyclotron radius (by two-dimensional azimuthal quadrupolar excitation at frequency \(w_c\)), then collisions will rapidly damp the cyclotron motion to zero, and ions will relax toward the central axis of the ion trap. The interconversion frequency is given by\(^\text{52}\)

\[
w_{\text{interconvert}} = \frac{3(2.66667)qV_{\text{quad}}}{2md^2(w_+ - w_-)} \quad \text{(SI units)}
\]  

(54)
or
\[
\nu_{\text{interconvert}} = \frac{9.77601 \times 10^6 z V_{\text{quad}}}{md^2(v_+ - v_-)} 
\]  \hspace{1cm} (55)

In Equations (54) and (55) the frequencies are in hertz, \( V_{\text{quad}} \) in volts, \( d \) in meters, \( m \) in unified atomic mass units, and \( z \) in multiples of elementary charge. The term \( \pm V_{\text{quad}} \) is the voltage applied to electrodes (separated by \( d \) meters), and 2.66667 is an ideal scaling factor corresponding to an infinitely extended tetragonal trap (\( \beta_{\text{quad}} \), see next section), in the configuration shown in Figure 11(b). For example, for ions of \( m/z = 1000 \), application of two-dimensional azimuthal quadrupolar excitation of \( \pm 1 \text{V} \) amplitude to electrodes separated by 2.54 cm in the configuration of Figure 11(b), at the unperturbed ion cyclotron frequency (107 500 Hz at 7.0 T), will interconvert magnetron and cyclotron motion at a frequency of \( \sim 141 \text{Hz} \). Thus, if those ions have zero initial cyclotron radius at time zero, then their magnetron motion will be completely converted to cyclotron motion in 0.5 \( \nu_{\text{interconvert}} \) or about 3.5 ms.

The conversion of magnetron motion to cyclotron motion, followed by collisional damping of the cyclotron radius has come to be known as quadrupolar axialization.\(^{3(2)}\) By shrink-wrapping a packet of ions initially distributed widely in radius (for instance as a result of ion initial formation or injection into the ion trap), axialization improves virtually every aspect of FTICR performance: mass resolving power and mass accuracy; cooling of ion internal energy; mass selectivity for MS\(^n\); CID efficiency; transfer efficiency in dual-trap experiments; and ion remeasurement efficiency. Ion remeasurement\(^{3(3)-5(6)}\) is especially useful for improving signal-to-noise ratio (and reducing the ICR detection limit)\(^{5(7)}\) and for high-resolution MS\(^n\)\(^{5(8)}\). Finally, quadrupolar axialization combined with nondestructive ICR detection enhances user-interactive FTICR/MS.\(^{5(9)}\)

### 7 EFFECT OF TRAP SIZE AND SHAPE ON DIPOLAR AND TWO-DIMENSIONAL QUADRUPOLAR EXCITATION

Equations (22–25) give the ion cyclotron radius \( r \), and translational (kinetic) energy, following single-frequency resonant azimuthal dipolar excitation by a spatially uniform RF electric field. To a good approximation, those equations also apply for similar excitation in a finite-size ion trap, by inclusion of a scaling factor \( \beta \) (Equations 56–60):

\[ r = \frac{\beta_{\text{dipolar}} E_0 T_{\text{excite}}}{2d B_0} \]  \hspace{1cm} (56)

or
\[ r = \frac{\beta_{\text{dipolar}} V_{\text{p-p}} T_{\text{excite}}}{2d B_0} \]  \hspace{1cm} (SI units)  \hspace{1cm} (57)

or, for broadband frequency-sweep dipolar excitation,
\[ r = \frac{\beta_{\text{dipolar}} V_{\text{p-p}} \sqrt{1/T_{\text{sweep rate}}}}{2d B_0} \]  \hspace{1cm} (58)

and
\[ \text{kinetic energy}_{\text{postexcite}} = \frac{\beta_{\text{dipolar}}^2 q^2 E_0^2 (T_{\text{excite}})^2}{8m} \]  \hspace{1cm} (SI)  \hspace{1cm} (59)

or
\[ \text{kinetic energy}_{\text{postexcite}} = \frac{1.20607 \times 10^7 \beta_{\text{dipolar}}^2 z^2 \times V_{\text{p-p}} (T_{\text{excite}})^2}{d^2 m} \]  \hspace{1cm} \times (1/\text{sweep rate}) \]  \hspace{1cm} (SI units)  \hspace{1cm} (60)

in which energy is in electron volts, \( V_{\text{p-p}} \) is in volts, \( T_{\text{excite}} \) is in seconds, \( d \) is in meters, \( m \) is in unified atomic mass units, and \( z \) is in multiples of elementary charge. For example, for single-frequency resonant excitation at 10 \( V_{\text{p-p}} \) for 400\( \mu \)s in a cubic Penning trap whose excitation plates are 2 cm apart, in a 7 T magnet field, the postexcitation cyclotron radius is 1.03 cm. Alternatively, ions having a wide range of mass-to-charge ratios may be excited to the same radius by frequency-sweep excitation (spanning the ICR frequencies of interest) of amplitude, \( V_{\text{p-p}} = 123 \text{V} \), at a sweep rate of \( 1.00 \times 10^7 \text{Hz s}^{-1} \). It is worth noting that the magnitude mode spectral peak height is proportional to \( 1/\sqrt{\text{sweep rate}} \).

Values of \( \beta_{\text{dipolar}} \) for several ICR traps in common use are shown in Table 1. Methodology for computing \( \beta_{\text{dipolar}} \) for orthorhombic, tetragonal, and cylindrical traps of arbitrary aspect ratio is available.\(^{4(4)}\)

Similarly, Equations (54) and (55) for the interconversion frequency for azimuthal two-dimensional quadrupolar excitation are rescaled as Equations (61) and (62). Values of \( \beta_{\text{quad}} \) for several ICR traps in common use are shown in Table 1, and formulas for computing \( \beta_{\text{quad}} \) for orthorhombic, tetragonal, and cylindrical traps of arbitrary aspect ratio have been published.\(^{4(4)}\)

\[ \nu_{\text{interconvert}} = \frac{3q \beta_{\text{quad}} V_{\text{quad}}}{2md^2 (v_+ - v_-)} \]  \hspace{1cm} (SI units)  \hspace{1cm} (61)

or
\[ \nu_{\text{interconvert}} = \frac{2.30342 \times 10^7 z \beta_{\text{quad}} V_{\text{quad}}}{md^2 (v_+ - v_-)} \]  \hspace{1cm} (62)
where frequencies are in hertz, \( V_{\text{quad}} \) in volts, \( d \) in meters, \( m \) in unified atomic mass units, and \( z \) in multiples of elementary charge.

Ideal scaling factors for all three potentials (dipolar excitation, quadrupolar excitation, and quadrupolar trapping) are closely approached by the potentials generated by the matrix-shimmed trap (see Figure 12). For example, \( \delta_{\text{dipolar}} \approx 1 \) for the matrix-shimmed trap. The matrix-shimmed trap consists of a cubic trap in which each side is segmented into a \( 5 \times 5 \) grid for a total of 150 electrodes. A near-perfect potential is then created by applying the appropriate voltage to each of these electrodes. The matrix-shimmed trap is an example of inverse logic and is discussed in the ion trap review paper by Guan and Marshall.\(^{(11)}\)

Although the matrix-shimmed trap is near-perfect in trapping, dipolar excitation, and quadrupolar excitation potential shape, its actual construction necessarily adds so much capacitance that its excitation and detection efficiency are unacceptably low.

### 8 MASS RESOLVING POWER, MASS RESOLUTION, AND MASS ACCURACY

The first derivative of Equation (5) with respect to \( m \) yields Equation (63),

\[
\frac{dw_c}{dm} = \frac{-qB_0}{m^2} = \frac{-w_c}{m}
\]

and hence Equation (64):

\[
\frac{w_c}{dw_c} = -\frac{m}{dm}
\]

It is usual in all types of FT spectroscopy to define resolution as the full width of a spectral peak at half-maximum peak height; namely, \( \Delta w_{50\%} \) or \( \Delta m_{50\%} \) for frequency-domain or mass-domain FTICR spectra. Because a valley just begins to appear between two peaks of equal height and shape when they are separated by slightly more than \( \Delta w_{50\%} \), or \( \Delta m_{50\%} \). The resolving power is then defined as \( w/\Delta w_{50\%} \) or \( m/\Delta m_{50\%} \). respectively. Equation (64) shows that the frequency resolving power and mass resolving power in ICR/MS are the same (except for a minus sign).

Because the frequency of an FTICR/MS peak is approximately \( qB_0/m \), the experimental mass resolution in Equation (64) can be expressed as Equation (65):

\[
\frac{m}{\Delta m_{50\%}} = -\frac{qB_0}{m\Delta w_{50\%}} \quad \text{(SI units)}
\]

It is useful to evaluate ICR mass resolution for either \( T \gg \tau \) (high-pressure limit) or \( T \ll \tau \), where \( T \) is the time-domain acquisition period and \( \tau \) is the time-domain exponential damping constant (Equation 31). The results are shown in Table 2. In the low-pressure limit, the time-domain ICR signal persists, undamped, throughout the acquisition period \( T \). In the high-pressure limit, the ICR time-domain signal damps essentially to zero during the acquisition period.

In the low-pressure limit, the corresponding FTICR mass spectral peak width is independent of \( m/z \). Thus, as \( m/z \) increases, the peak width remains relatively constant, but the peaks are closer together, because ICR frequency varies inversely with \( m/z \). That is why (see Equation 64 and Table 2), for a given ion–neutral collision frequency, ICR mass resolving power (at constant \( B_0 \) for a given \( T_{\text{acq}} \)) varies inversely with \( m/z \), as shown in Figure 15.

It is worth noting that Figure 15 applies to other magnet-based mass separators (notably magnetic sector mass spectrometers). However, in magnetic sector MS, it is usual to vary the magnetic field strength in order to bring ions of a given \( m/z \) into focus. In that case, magnetic sector mass resolving power might follow one of the dashed lines in Figure 15 (i.e. if FTICR and magnetic sector mass resolving power are the same at \( m/z \) 1000, then the sector resolving power will remain constant throughout the \( m/z \) range, whereas the FTICR resolving power will increase with decreasing \( m/z \)). Thus, FTICR/MS achieves the highest mass resolution possible for magnet-based mass analysis, by operating at maximum magnetic field strength throughout the mass range. (A fixed-field magnet also produces a spatially more homogeneous field, thereby further increasing the mass resolving power.)

### Table 2 The FTICR mass resolution \( \Delta m_{50\%} \), and mass resolving power \( m/\Delta m_{50\%} \), in which \( \Delta m_{50\%} \) is the full magnitude-mode FTICR/MS peak width at half-maximum peak height.\(^{(16)}\) The factor \( T_{\text{acq}} \) is time-domain ICR signal acquisition period, and \( \tau \) is the collisional damping constant (Equation 31)

\( (m/z \text{ in unified atomic mass units per elementary charge}) \)
Because an ion trap must contain side electrodes in order to provide for excitation and/or detection of the ICR signal, it is clear that the ultimate upper mass limit is the mass at which the ion cyclotron radius of a thermal ion reaches the radius of the trap. Equation (10) gives the cyclotron radius of an ion of average thermal translational energy $kT$, from which we can solve for the highest mass ion for which the cyclotron radius is less than the trap radius $d/2$. Rewriting Equation (10) we find that at 7.0 T, the upper mass limit for a singly charged room-temperature ion would be about 5.89 MDa in a trap of 1 in cross-sectional radius (Equations 66 or 67):

$$m_{\text{upper}} = \frac{q^2 B_{\text{max}}^2 r^2}{2kT} \quad \text{(SI units)}$$  \hspace{1cm} (66)

or

$$m_{\text{upper}} = 5.598 \times 10^{11} \frac{z^2 B_{\text{max}}^2 r^2}{T} \quad \text{(atomic units)}$$  \hspace{1cm} (67)

where $r$ is in meters, $B_0$ in Tesla, $m$ in unified atomic mass units, $T$ in Kelvin, and $z$ in multiples of elementary charge. Of course, the actual upper mass limit will be smaller, because ions must begin with an ICR orbital radius much smaller than that of the trap in order that a detectable coherent signal be generated by exciting their cyclotron orbital motion to a larger radius for detection.

9.2 Trapping Potential Mass Limit

Equation (66) is valid only in the absence of electric field (from either the applied electrostatic trapping potential or Coulomb repulsions between ions). In the presence of a three-dimensional axial quadrupolar electrostatic trapping potential, Figure 14 shows the magnetron, reduced cyclotron, and trapping oscillation frequencies as a function of $m/z$. Analysis of Equations (49–52) shows that the magnetron and reduced cyclotron frequencies converge to a common value, $w_{\text{m}} = \omega_{\text{c}} / \omega_{\text{trap}} = qB_0 / 2m$, at the so-called critical $m/z$ (49), namely, when Equation (68) holds:

$$\frac{w_c^2}{2} = \frac{w_{\text{trap}}^2}{2}$$  \hspace{1cm} (68)

or

$$m_{\text{critical}} = \frac{qB_0^2 a^2}{4V_{\text{trap}} \alpha} \quad \text{(SI units)}$$  \hspace{1cm} (69)

$$m_{\text{critical}} = \frac{1.20607 \times 10^7 \omega_{\text{c}} B_0 a^2}{2V_{\text{trap}} \alpha}$$  \hspace{1cm} (70)

In Equations (69) and (70) $\alpha$ is in meters, $B_0$ in Tesla, $m$ in unified atomic mass units, $V_{\text{trap}}$ in volts, and $z$ in multiples of elementary charge.

For $m/z > m_{\text{critical}}$, ion cyclotron motion is no longer stable, and the ion spirals outward until it is lost from the trap. For example, at 7.0 T, for $V_{\text{trap}} = 1$ V applied to a cubic trap ($\alpha = 2.773$) of $a = 2.54$ cm, $m_{\text{critical}} = 274 \, 000$ z. Figure 16 shows the dependence of $m_{\text{critical}}$ on trapping voltage, at each of five magnetic field strengths. (The actual upper mass limit in each case is slightly lower if we specify that (say) 99% of thermal ions fit within the 1 in separation between the detector electrodes.) Figure 16 also shows the desirability of cooling ions so that the trapping potential may be lowered, thereby increasing the upper mass limit.

9.3 Trapping Potential Energy Limit; Space Charge and the Peak Coalescence Mass Limit

Obviously, ions with translational energy higher than the potential well depth (which in turn scales linearly with the trapping potential applied to each end cap electrode) can escape axially from the trap. That problem may be solved by increasing the trapping voltage; however, it is also possible to trap too many ions. In fact, when more than about 10,000 ions are present in the trap, it becomes...
necessary to consider the static and dynamic effects of ion–ion repulsions. It can be shown that in a spatially uniform static electromagnetic field, Coulomb repulsions between ions do not affect the ICR orbital frequency of the ion packet.\(^{[61]}\) However, in the spatially nonuniform electromagnetic field of a typical ion trap, Coulomb repulsions can shift and broaden FTICR mass spectral peaks, by pushing like-charge ions apart into regions of different applied external electric or magnetic field.

Peak coalescence (i.e. observation of a single FTICR mass spectral peak whose width is narrower than the separation between ions) occurs when two ion clouds have sufficiently large ion populations and very similar mass-to-charge ratios (Figure 17). Theoretically, for two very long cylindrical ion clouds whose single-ion cyclotron radius \(R_c\) and ion cloud radius \(r_c\) are initially overlapping, the ion clouds coalesce if the difference in cyclotron frequency, \(w_2 - w_1\), between the two clouds is (Equation 71)

\[
\Delta w_c < \frac{N_1 q_1 + N_2 q_2}{2\pi\varepsilon_0 L B_0 R_c s_{\text{eff}}} \tag{71}
\]

in which \(\varepsilon_0\) is the vacuum permittivity, \(N_1 q_1\) or \(N_2 q_2\) is the total charge contained in each cylinder, \(L\) is the length of cylinder, and \(B_0\) is the magnetic field induction. \(s_{\text{eff}} \approx 1.04\rho_c\) is calculated numerically, based on an initial separation between the two ion clouds of the order of the ion cloud radius \(\rho_c\).\(^{[63]}\) Thus, the tendency for two ion clouds to coalesce to a single experimentally observable ion cyclotron frequency varies directly with the number of ions in each cloud, and inversely with magnetic field

\(-\)

\(m/z\) for which an ion has a stable orbit, independent of ion initial velocity (temperature).

Figure 16 Upper mass limit for a singly charged ion in a cubic Penning trap, for each of five common magnetic field strengths: 1.0, 3.0, 4.7, 7.0, and 9.4 T. At \(V_{\text{trap}} = 1\) V, each arrow denotes the highest \(m/z\) for which an ion has a stable orbit, independent of ion initial velocity (temperature).

Figure 17 Coulomb-mediated peak coalescence. (a) Matrix-assisted laser desorption/ionization (MALDI) FTICR magnitude-mode mass spectrum of quasimolecular ions, \((M + H)^+\), of partially deuterated leucine enkephalin. Although mass resolving power greater than 550000 has been achieved (the experimental peak in (b)), the \(^{12}\text{C}^{32}\text{H}^{13}\text{C}^{1}\text{H}\) doublet is not resolved (the theoretical doublet computed from two magnitude-mode Lorentzians at a resolving power of \(m/\Delta m_{50\%} \approx 550000\) in (b)), due to the Coulomb interaction of ions of two nearly identical mass-to-charge ratios. (Reproduced with permission from Pasa-Tolic et al.\(^{[62]}\))

\[ m_{\text{max}} \approx 3.2 B_0 \frac{\varepsilon_0 LR_c \rho_c \Delta m}{N_{\text{ave}}} \quad \text{(SI units)} \tag{72} \]

\[ m_{\text{max}} \approx 2.333 \times 10^5 B_0 \frac{LR_c \rho_c \Delta m}{N_{\text{ave}}} \tag{73} \]

where \(L, R_c,\) and \(\rho_c\) are in centimeters, and \(m\) in unified atomic mass units. The factor \(N_{\text{ave}} = (N_1 + N_2)/2\) is the average number of ions in the two clouds. Equation (72) leads to a particularly useful theoretical prediction, namely, that the highest mass at which ions whose masses differ by 1 Da begin to coalesce is about 100000\(B_0\) Da.\(^{[64]}\)

Although based on a highly idealized theoretical model
(and therefore not to be taken too literally), Mitchell’s result provides good insight into the variables that affect peak coalescence.

10 ION SOURCES

10.1 Internal Ionization

Successful application of the FTICR/MS technique requires ionization and trapping of the species of interest. For volatile compounds these processes may be achieved by leaking the corresponding neutral vapor into the volume of the ion trap (either through a valve or by applying less volatile substances to a probe surface, positioning the probe adjacent to the ion trap, and heating to vaporize the substance) and ionizing in situ (known as internal ionization). The most common internal ionization technique is electron ionization (EI) (photoionization (PI) is also in use). In EI, an electron beam of controllable energy and current (typically 70 eV and \(\sim 1\,\mu\text{A}\)) is directed through the center of the ion trap for a specified time period. The interaction between the electrons and neutral molecules can result in either ejection of a valence electron to form positive ions or (for very low energy electrons) electron capture to form negative ions. The electron beam can also be used to perform chemical ionization (CI), in which a suitable reagent is ionized by the electron beam and then undergoes proton or electron transfer to form a chemically ionized analyte. PI is typically performed in the same manner but with a suitable light source (i.e., laser, arc lamp, etc.) directed along the central axis of the ion trap (although not required, ions are almost always formed or injected along the central trap axis for optimal FTICR performance). These techniques were the first to be implemented with FTICR mass analysis, and have provided ions for a voluminous number of studies relating to ion-molecule reaction pathways, ion structure and energetics, kinetics, and compound identification.\(^{65–70}\)

10.2 External Ionization

Although internal ionization methods encompass a wide range of experiments, it is often desirable to couple FTICR mass analysis with ion sources that form ions outside the trap, mainly because nonvolatile substances that are not amenable to heating can be effectively desorbed into the gas phase and ionized (e.g., metals, peptides, proteins, oligonucleotides, oligosaccharides, lipids, synthetic polymers, etc.). These external (to the ICR trap) ionization methods may be divided into two categories. In the first, the nonvolatile substance is deposited on a probe surface and the probe is positioned adjacent to the ion trap. A desorption/ionization event follows and the resulting ions can be directed toward the trap and captured. Examples include laser desorption/ionization (or laser desorption of neutrals followed by EI\(^{71}\)) and MALDI\(^{72–74}\), as well as many others.\(^{75–79}\) The second class of external ionization techniques operates at such high pressure (>1 torr) that the ion source must be separated from the ion trap by several stages of differential pumping in order to achieve the necessary low pressure (<1 \times 10^{-8}\text{torr}) required for optimal mass analysis. These methods include EI\(^{80,81}\), cluster sources,\(^{82}\) and high-pressure sources.\(^{83,84}\) The multiple pumping stages usually require that the source be located outside the solenoidal ICR magnet (although there is an exception\(^{85}\)) so that ions formed by these methods are injected through the magnetic fringe field by a suitable ion guide (electrostatic Einzel lenses,\(^{31,32}\) multipole RF ion guides,\(^{86}\) and DC wire ion guides\(^{12,13}\) have been used). Although more complex, the ion guides have worked well enough that many ionization techniques that can be located inside the magnet have also been implemented outside the magnet\(^{87,88}\) usually for convenience in accessing the ion source.

10.3 Chromatographic Interfaces

The FTICR/MS technique is capable of powerful mixture analysis due to its high mass range and ultra-high mass resolving power. However, in many cases it is still desirable to couple a chromatographic interface to the mass spectrometer for sample purification, preconcentration, and mixture separation. The first separation technique to be coupled with FTICR was gas chromatography (GC).\(^{89}\) The GC effluent is admitted into the ion trap region of the vacuum chamber and ions are formed with an electron beam. More recent efforts have focused on liquid chromatography (LC)\(^{90–92}\) and capillary electrophoresis (CE),\(^{93}\) both coupled to the mass spectrometer by use of EI. These couplings have produced exciting new advances in the analysis of biopolymers present in complex biological matrices.\(^{90,94}\)

11 TANDEM MASS SPECTROMETRY METHODS

MS/MS consists of activation of primary (parent) ions, resulting in dissociation or reaction followed by mass analysis of the resulting secondary (product) ions.\(^{145}\) In an FTICR instrument, activation is commonly achieved by the following: collisions of ions with neutrals (CAD or CID)\(^{95}\) or surfaces (surface-induced dissociation (SID))\(^{54,55,72,73,96}\) ultraviolet photodissociation
(UVPD); multiphoton infrared photodissociation (IRMPD); or blackbody infrared dissociation (BIRD). For CAD (CID) of macromolecular ions, the most popular method is sustained off-resonance irradiation (SORI), although very low-energy (VLE) and multiple excitation collisional activation (MECA) are also available. Figure 18 shows that SORI, VLE, and MECA each provide for periodic excitation of ion cyclotron radius (and thus ion translational energy) to an adjustable maximum value; SORI tends to be preferred, probably because it is simplest to implement and tune.

Photodissociation of large biomolecules has also proved effective for biomolecule characterization. Typically infrared (IR; 10.6 µm) laser photons are used for slow heating and fragments similar to those obtained by CAD are produced. One advantage of IRMPD is that gas pulses are not necessary, so that high-resolution FTICR detection can occur quickly after dissociation (no pumpdown is required). An alternative to laser photodissociation takes advantage of the blackbody radiation produced by a heated vacuum chamber (BIRD). Ions are confined in the hot ICR trap (10–1000 s), where ion structure- and temperature-dependent interaction with the blackbody radiation occurs. A unique feature of BIRD is that the ion cloud assumes a known (i.e. Boltzmann) and controllable internal energy distribution. Thus, information on dissociation energetics and mechanisms can be obtained from the temperature dependence of the unimolecular dissociation rate constants.

Finally, SID has been investigated as a probe of ion structure by FTICR/MS. The advantage of SID is the potential for high internal energy deposition with a relatively narrow distribution. However, results to date indicate that collection of product ions is difficult and that unique structural information is rarely obtained.

**Figure 18** Time evolution of ion cyclotron radius (left) and ion trajectory (right) for each of three ICR techniques for ion multiple activation based on repeated single-frequency dipolar excitation for CID. (a) In SORI, ions of a selected m/z ratio are alternately excited and de-excited due to the difference between the excitation frequency and the ion cyclotron frequency. (b) In VLE CID, ions are alternately excited and de-excited by resonant excitation whose phase alternates bimodally between 0° and 180°. (c) In MECA, ions are resonantly excited and then allowed to relax by collisions. (Reproduced with permission from Guan and Marshall.)

**12 ADVANTAGES OF HIGH MAGNETIC FIELDS**

It was noted above that mass resolving power in FTICR/MS increases linearly with increasing applied magnetic field induction B for fixed ion–neutral collision frequency. In fact, seven other FTICR primary performance parameters theoretically also increase linearly (data acquisition speed, upper mass limit for peak coalescence) or quadratically (upper mass limit due to trapping potential, maximum ion kinetic energy, maximum number of trapped ions, maximum ion trapping duration, two-dimensional FTICR mass resolving power) with increasing B (Figure 19). Two-dimensional FTICR/MS, such as two-dimensional nuclear Overhauser effect NMR spectroscopy, provides an automated method for determining ion–molecule reaction pathways, kinetics, and equilibria simultaneously for all primary ions in a mixture. The origin of (and conditions for) the magnetic field dependence of each of these parameters have been collected and discussed. These fundamental advantages lead to corollary improvement in other FTICR performance parameters, such as signal-to-noise ratio, dynamic range, mass accuracy, ion remeasurement efficiency, and mass selectivity for MS/MS. Finally, these various advantages may be exploited in combination, so as to produce even higher enhancement in a particular parameter; for instance, the signal-to-noise ratio can improve by more than a factor of B² if the mass resolving power is fixed at the same value as at lower magnetic field.
FOURIER TRANSFORM ION CYCLOTRON RESONANCE MASS SPECTROMETRY

13 FOURIER TRANSFORM SPECTROSCOPY ASPECTS

The FTICR/MS technique shares many common conceptual and data reduction features with other types of FT spectroscopy, as has been discussed in depth. The homology between FTICR and FTNMR is deep and virtually complete. The most unique advantage of FTICR as a mass analyzer is that the ion mass-to-charge ratio is experimentally manifested as a frequency. Because frequency can be measured more accurately than any other experimental parameter, ICR/MS therefore offers inherently higher resolution (and thus higher mass accuracy) than any other type of mass measurement. The introduction of FT techniques to ICR/MS brought not only the Fellgett (multichannel, opening the exit slit) advantages of increased speed (factor of 10,000), or increased sensitivity (factor of 100), but also the advantages of fixed magnetic field rather than swept field, namely increased mass resolution (factor of 10,000), and increased mass range (factor of 500). Applications deriving from these advantages include determination of chemical formulas (particularly in complex mixtures), detection limit in the attomole range, and multistage MSⁿ.

FT manifestations in ICR include: Nyquist sampling and foldover; fast FT; zero-filling; windowing or apodization; deconvolution; oversampling; and two-dimensional Hadamard transform. In addition, various non-FT methods for obtaining a frequency-domain (and thus mass-domain) spectrum from a time-domain interferogram ICR signal include: the Hartley transform (a way of performing a FT on real-only data); the Bayesian maximum entropy method (MEM); and linear prediction.

However, several aspects of FTICR data reduction differ from those of FT interferometry or FTNMR spectroscopy. Notably, the phasing of FTICR spectra over a broad frequency range is difficult; thus, spectra are usually reported in magnitude mode rather than absorption mode. As a result, resolving power is lower than for absorption mode by a factor ranging from about \( \sqrt{3} \) (Lorentzian peak shape) to 2 (sinc peak shape), and new peak-fitting algorithms have been developed. Apodization of magnitude-mode spectra has been performed by means of magnitude-mode multiple-derivative techniques. Moreover, FTNMR is conducted exclusively in heterodyne-mode, whereas FTICR/MS is often performed by sampling the ICR signal directly without heterodyning. Due to the need for massively large datasets (several megawords of time-domain data) to take advantage of potentially ultrahigh mass resolving power over a wide mass range, data clipping (to as low as 1 bit/word) has been demonstrated, with only modest distortion of the FT spectrum. Finally, the ICR time-domain signal typically exhibits non-exponential damping; hence, it is common to apodize the time-domain signal with a window function (e.g. Blackman-Harris) that preferentially damps the initial portion of the time-domain signal prior to Fourier transformation.

14 RELATION TO PAUL (QUADRUPOLE) ION TRAP

The close relation between Penning (ICR) and Paul (quadrupole) ion traps is perhaps most evident from the 1989 Nobel Prize, which was shared by Dehmelt and Paul, the two most famous developers of the two techniques. Many trapped-ion techniques first introduced in FTICR have since been adapted to the Paul trap, including: CID of trapped ions; mass-selective ion ejection; frequency-sweep excitation; stored-waveform excitation/ejection; FT detection of an induced image current; and the interfacing of various ion sources to the mass analyzer.
15 SELECTED APPLICATIONS

15.1 Elemental Composition from Accurate Mass Measurement

A powerful advantage of FTICR over other mass analyzers is accurate mass capability. For singly charged ions of below 700 Da, a unique elemental composition can be assigned directly from the measured mass if ~1 ppm mass accuracy can be achieved.\(^{(19,137)}\) An example is shown in Figure 20, in which EI FTICR mass analysis of raw diesel fuel feedstock resolves ~500 singly charged ion masses in the range 90–300 Da. The ultrahigh resolving power afforded by FTICR/MS reveals several different species at each nominal mass. With proper mass calibration (see Equation 53), the elemental composition of each species can be assigned unambiguously based on sub-ppm mass accuracy. Elemental composition is critical in such analyses because it is important to identify and monitor sulfur- and nitrogen-containing species as they are removed during the fuel purification process.

15.2 Detection Limit for Biological Analysis

A fundamental limit of FTICR broadband image current detection is that typically about 100 ions of a given mass-to-charge ratio are required to induce a measurable signal. Ion counting (destructive-detection) mass spectrometers are therefore inherently more sensitive. However, the FTICR detection limit can still be spectacularly low. With CE coupling, Hofstadler et al. acquired hemoglobin mass spectra from a single red blood cell (containing about 450 amol of hemoglobin).\(^{(94)}\) An even lower detection limit has been achieved, where CE/FTICR mass spectra have been observed from sub-attomole protein samples.\(^{(138)}\) Further, the same researchers used a CAD spectrum from 9 amol of carbonic anhydrase and database searching to unambiguously identify the protein in spite of N-terminal acetylation. Although lower detection limits have been obtained with other mass analyzers, the unique combination afforded by accurate mass measurement, ultrahigh resolution, and nondestructive detection allowing for MS\(^n\) in combination with a very low detection limit makes FTICR extremely attractive for biological analysis.

A key feature common to these impressive results is the CE coupling. However, a major disadvantage of CE sample introduction is the requirement of a fairly concentrated analyte solution. The LC/FTICR method is an attractive alternative for the very dilute solutions often encountered in biological samples. Figure 21 shows a selected-ion chromatogram and mass spectra from LC/FTICR mass analysis of a three-component peptide mixture.\(^{(139)}\) Each of those peptides was present at 500 pM concentration in a 100 mM salt aqueous matrix! Sample loading onto a specially designed nano-LC column/microelectrospray tip facilitates sample desalting, preconcentration and gradient separation.\(^{(140)}\)

Samples were dissolved in artificial cerebrospinal fluid at 500 amol µL\(^{-1}\) each and loaded (10 µL) onto a C\(_{18}\) packed micro-ESI needle. The reconstructed ion chromatogram is shown below, with ESI/FTICR mass spectra of individual peptide spectra shown as insets. (Reproduced from Emmett et al.\(^{(139)}\))
15.3 High Mass

Multiple-charging inherent to ESI has revolutionized the mass analysis of large molecules. Typically the highest-mass species carry the greatest number of charges, thereby yielding ions with mass-to-charge ratio \(500 < m/z < 2500\), especially favorable for FTICR detection even at very high ion mass. The combination of ESI with FTICR detection has yielded striking results in the analysis of large ions. Unit mass resolution and accurate mass analysis are now routine for proteins as in the analysis of large ions. Unit mass resolution and accurate mass analysis are now routine for proteins as in the analysis of large ions. Unit mass resolution and accurate mass analysis are now routine for proteins as in the analysis of large ions.

In that work, the masses of two chondroitinase enzymes were determined with 3 Da accuracy, information that helps in obtaining FDA approval for use of the enzymes as drugs. Finally, trapping and detection of a single 100 MDa DNA ion with around 30 000 charges has been achieved. (146)

15.4 Isotopic Amplification for Unit Mass Accuracy of Biomacromolecules

Several related problems arise from the presence of multiple isotopes in biological macromolecular ions. First, a typical electrospray-ionized protein can take on about one proton per kilodalton, by protonation of available arginine and lysine residues. Because mass analyzers in general (and ICR in particular) separate ions based on mass-to-charge ratio \((m/z)\), in which \(m\) is ion mass in unified atomic mass units and \(z\) is charge in multiples of the elementary charge), the first problem is how to determine charge independent from mass. Fortunately, if the isotopic envelope can be resolved to better than 1 u (Figure 22a), adjacent peaks differ by \(m/z = 1/z\); thus, the ion charge may be obtained simply as the reciprocal of the spacing between two adjacent peaks in the \(m/z\) spectrum. (147) Because only FTICR/MS can resolve such multiplets for macromolecular ions of more than a few kilodaltons, FTICR/MS is the method of choice for mass analysis of such species.

A second (more vexing) problem is that even if \(m/z\) for each of the resolved isotopic peaks can be determined to ppm accuracy, the molecular weight can still be in error by a whole dalton or more, because (except for the lowest-mass monoisotopic species – namely, the unique elemental composition for which all carbons are \(^{12}\)C, all nitrogens are \(^{14}\)N, all oxygens are \(^{16}\)O, all sulfurs are \(^{32}\)S, etc.), it is necessary to match the observed isotopic abundance distribution to that predicted for, for instance, a protein of average amino acid composition. (148) However, if the relative abundances are just a bit in error, or if the unknown protein differs in composition

Figure 22 The ESI/FTICR mass spectra of chondroitinase I. (a) Mass scale-expansion showing unit mass resolution of the isotopic distribution of the \(z = 91\) charge state. (Data kindly provided by N. Kelleher and described in detail elsewhere.) (b) Heterodyne data for SWIFT-isolated ions, \(1226 < m/z < 1273\), with external ion accumulation from 10 co-added time-domain signals; the peaks at \(m/z\) 1240 and 1254 correspond to an unidentified adduct of \(\sim 260\) Da.

Figure 23 The ESI/FTICR mass spectra (9.4 T) of a mutant (C22A) FK506-binding protein. (a) Natural-abundance isotopic distribution (\(\sim 98.89\% {^{12}\text{C}}; \sim 99.63\% {^{14}\text{N}}\)). (b) Isotopic distribution for the same protein grown on a medium with 99.95\% \(^{15}\)C and 99.99\% \(^{15}\)N. Insets: Isotopic distributions calculated (same vertical scale) from the chemical formula for natural-abundance (a) and \(^{13}\)C, \(^{15}\)N doubly depleted (b) FK506 binding protein. (Reproduced with permission from Marshall et al.)
from the average protein in the database, then the estimated molecular weight can be in error by one or more daltons.

A simple solution to the above problem is to express a protein from a minimal medium containing $^{13}$C-depleted glucose and $^{15}$N-depleted ammonium sulfate. An example is shown in Figure 23. Both simulated and experimental electrospray FTICR mass spectra show that double-depletion of $^{13}$C and $^{15}$N effectively narrows and shifts the isotopic distribution to the left, so that the monoisotopic species is now prominent and easily identified.$^{(149)}$ This technique promises to extend the upper mass limit for protein MS by about an order of magnitude, and is optimally exploited only by FTICR/MS.$^{(149)}$ By measuring protein mass accurately to within 1 Da, it becomes possible to: count the number of disulfide bridges ($\sim -S-S- \sim$ is 2 Da lighter than two $\sim -SH$); identify deamidation ($\sim -NH_2$ is 1 Da lighter than $\sim -OH$); identify post-translational modifications and noncovalent adducts; and identify proteome components directly without prior two-dimensional gel separation.

Gas chromatography/mass spectrometry (GC/MS) is perhaps the most widely used analytical technique for the analysis of complex mixtures. The power of this technique stems from the "marriage" of two powerful techniques into a hyphenated method. Gas chromatography (GC) is used to separate the components of a mixture based on their differing affinities for the stationary phase on the column. Mass spectrometry (MS) serves not only to detect and quantify the various species eluting off the column but also provides definitive information as to their identity. The most common GC/MS instruments employ a gas chromatograph with a split/splitless injector, capillary column, and either a quadrupole or quadrupole ion trap as a mass analyzer. A high degree of automation and a powerful data system are required for handling the large amounts of three-dimensional (3-D) data (time, mass-to-charge ratio (m/z) and intensity) that can be generated. The technique typically requires that the analytes in question have sufficient volatility to be amenable to GC. It is very sensitive, with detection limits typically in the picogram or even sub-picogram range. It can be highly selective and allows for incredible flexibility with respect to the type and quality of the mass spectral data; the user may choose from a number of ionization modes and scan modes, and control mass range and mass resolution, and many other experimental parameters. Analysis speeds are relatively slow due to the time required for adequate chromatographic separation, but can be reduced to an order of a few minutes using fast GC techniques. GC/MS instrumentation is usually intended for benchtop operation in the laboratory, although a number of field-portable instruments have been developed. The technique requires significant user expertise, knowledge of various means for compound identification and quantitation, and instrument tuning, maintenance, and upkeep.

1 INTRODUCTION

GC/MS is perhaps the most successful of all the so-called hyphenated techniques. GC separates compounds on the basis of their differing affinities for the stationary phase. MS records the separation process and three dimensions of information: time, mass-to-charge ratio (m/z) and intensity. Identification of individual compounds is usually achieved through the combination of a retention time match with a known standard and a match of the experimental electron ionization (EI) mass spectrum against a library spectrum. Quantitation is usually performed by ratioing the response of a selected quantitation or "quan" ion in the sample to that of a standard of known concentration. The combination of GC with MS represents the most powerful and widely used technique for the analysis of complex mixtures. Its primary applications include the analysis of drugs, explosives, pesticides, petroleum products, and pollutants in air, water and soil; and its uses encompass such diverse areas as clinical chemistry, environmental science, food and beverage analysis, forensic science, industrial hygiene, and process monitoring.

GC/MS necessitates that the target compounds of interest be amenable to GC analysis (i.e. relatively low molecular weight, nonlabile, thermally stable, reasonably volatile or derivatizable). The sensitivities of MS detectors are either comparable with or better than many other GC detectors, with the notable exceptions being the electron capture detector (ECD) and other highly selective GC detectors. Selectivity in GC/MS analyses is outstanding and in many cases can provide conclusive evidence for the presence of a compound due to the combination of the orthogonal information from GC and the structural information from MS. Selectivity and sensitivity can be further enhanced through the use of selective chemical ionization (CI) techniques and/or selected ion monitoring (SIM).
and mass spectrometry/mass spectrometry (MS/MS) scan modes. The technique is mature, robust, and the method of choice for an incredibly wide variety of applications.

From an historical perspective, some of the early success of GC/MS can be traced to a number of advances. These include the interfacing of a gas chromatograph to a quadrupole mass analyzer, the development of the first computerized data acquisition and mass spectral library searching software, and the acceptance of GC/MS as the method of choice for the 600 method series by the United States Environmental Protection Agency (USEPA).\(^2\text{–}^4\)

In the past decade, GC/MS has evolved from a technique that had been mainly used by scientists with training in MS to a more general-purpose GC detector requiring minimal operator expertise. The main reasons for this are the proliferation of low-cost, benchtop GC/MS instruments equipped with powerful, user-friendly software to facilitate instrument control and data analysis. The ever-growing number, and types, of GC/MS applications has and will continue to drive the evolution of sample introduction systems, improved analytical figures of merit, “smart” autotuning procedures and diagnostic routines, and highly automated chemical analyses.

The difficulties posed by deciding on the proper context for a discussion on GC/MS are perhaps best represented by Eiceman et al. who asked “Is gas chromatography an inlet for mass spectrometry, or is mass spectrometry a detector for gas chromatography?”\(^5\) A number of books on MS detail the many facets associated with GC/MS.\(^6\text{–}^{12}\) Fundamental and application reviews describing recent advances in GC,\(^5\) MS,\(^13\) and their applications\(^14\) are published biannually in Analytical Chemistry. Primary research articles are provided in a wide array of scientific journals too numerous to list here. For the purposes of brevity, this article will discuss a limited number of topics most relevant to the theory and practice of GC/MS. The individual instrumental components required for GC/MS will be described. These include sample introduction systems, gas chromatographs, and mass spectrometers. Data analysis including compound identification, quantitation, and artificial intelligence-based (AI) systems will be discussed. The article concludes with a discussion of practical considerations and future prospects.

2 GAS CHROMATOGRAPHY/MASS SPECTROMETRY INSTRUMENTATION

A simplified schematic diagram of a GC/MS instrument is shown in Figure 1. It may include a specialized sample introduction system for various applications (e.g. air concentrator for analysis of volatile organics in air, purge and trap module for analysis of purgable organics in water). Other components include a gas chromatograph, mass analyzer, and control computer. Each of these components is discussed here from the standpoint of requisite instrumentation. This discussion is limited to those issues most germane to GC/MS analyses, specifically sample introduction systems, GC injectors and columns; mass analyzers, ionization modes, and scan

Figure 1 Block diagram of a GC/MS system.
2.1 Sample Introduction Systems

In most applications, the sample workup procedure results in injection of a sample containing the analytes of interest on to the head of the column for subsequent GC/MS analysis. Examples of this might include a gas sample, biological extract, or a soil sample extract. In some cases, the sample requires special treatment or derivatization prior to injection on to the head of the column. This section discusses the more widely used sample introduction systems for GC/MS analyses.

2.1.1 Air Concentrators

Increased interest is being paid to monitoring the types and concentrations of a variety of volatile organic compounds (VOCs). The revisions to the Clean Air Act in 1990 and increased interest in the sources, transport, and fate of a variety of anthropogenic and biogenic hydrocarbons have similarly led to a large number of ongoing efforts to collect data on the types and concentrations of these compounds. It should be noted that GC coupled with some detector other than a mass spectrometer is often entirely appropriate for analyses of specific target compounds in well-characterized samples. To give a couple of examples, GC coupled with flame ionization detection (FID) is widely used for the analysis of various hydrocarbons in gasoline, and GC coupled with ECD provides a very sensitive, selective means for monitoring halogenated species such as dioxins, polychlorinated biphenyls (PCBs), and pesticides. Such one-dimensional (1-D) GC detectors are usually unable to provide conclusive information as to the identity of unknown species in uncharacterized samples. In these cases, MS is a better detector due to the wealth of structural information it can provide.

Air samples can be collected by a variety of means. For whole air samples, Tedlar bags or stainless steel canisters are employed. For higher molecular weight VOCs (typically containing six or more carbons), a sorbent trap is used, with the sorbent agent being selected on the basis of its ability to trap the VOCs of interest. Once collected, the samples are analyzed by standard USEPA methods. Details on the sorbent-trap-based methods are provided in USEPA TO-1 and TO-2, whereas the Tedlar bag or canister-based methods are covered by USEPA TO-14. The analysis for VOCs in air samples involves a number of discrete steps. In the case of samples collected in Tedlar bags or canisters, a known volume of the sample is passed through a cryogenically cooled internal trap, which traps the VOCs while passing the bulk constituents of air (i.e. nitrogen and oxygen). In the case of samples collected on sorbent traps, the VOCs are thermally desorbed on to the cryogenically cooled internal trap. Next, the VOCs are thermally desorbed on to the head of a column. In some cases, water and carbon dioxide removal steps are employed during this process to prevent clogging of the transfer lines with ice and improve chromatographic resolution of early eluting compounds. When employing a standard bore (0.25 mm internal diameter (ID)) column, a final cryofocusing step must be used to focus VOCs on to the head of the column for subsequent desorption, to minimize zone broadening and maintain chromatographic resolution.

In years past, numerous research groups developed their own air concentrators using a relatively simple system that included a sample loop which was immersed in liquid nitrogen to trap the air sample and then rapidly heated to desorb the VOCs on to the column. In more recent years, a number of commercial air concentrators have become available. The more popular models provide separate inlets for introduction of samples and internal standards; include separate modules for removal of both water and carbon dioxide; utilize heated, specially treated (silylated or silico-grade) stainless steel for the entire sample path; and are highly automated. Nevertheless, these devices are expensive, require constant attention to ensure proper operation (e.g. ensuring that background levels are low, there is minimal carryover, etc.), and often necessitate ancillary equipment (e.g. cryofocusing module, canister cleaning system, sorbent trap conditioner, etc.). Used properly, they can provide part-per-trillion (ppt) level detection limits, minimal band broadening, and reliable results.

2.1.2 Liquid Purge and Trap

Liquid purge and trap GC is a mature, widely used technique for routine water quality testing, the analysis of off-odors in foods and beverages, and other applications. The heart of this technique is the concentration of purgable organic compounds from a headspace above a liquid sample on to a sorbent trap, which is subsequently heated to desorb and release these concentrated organics on to the head of a GC column. The bulk of these analyses are based on USEPA methods 601, 602, 501, and 502. A number of vendors offer automated liquid purge and trap devices, ranging from compact units that can be mounted directly on to the GC to larger units that can handle multiple samples. As with air concentrators, these devices work well for their intended applications, provide a high degree of automation, and can achieve sub-part-per-billion (ppb) level detection limits.
2.1.3 Solid-phase Microextraction

In the past, routine analyses of extractable organic compounds in aqueous-based samples and soil samples usually required time-consuming and arduous Soxhlet, liquid–liquid, and liquid–solid extraction techniques. The development of new solid-phase extraction (SPE) and the more recent solid-phase microextraction (SPME) techniques have greatly changed the way these analyses are performed. SPE techniques are probably more accurately characterized as sample preparation techniques which are used prior to GC/MS analysis and hence are not discussed further here. Although SPME is likewise a sample preparation technique, SPME cartridges can be used to extract the compounds of interest and then directly inject the extract into the GC/MS instrument. Hence their discussion is deemed appropriate here as a sample introduction system for GC/MS.

SPME is appropriate for the analysis of either volatile or semivolatile compounds in various matrices. It has been used for a wide variety of applications including analysis of VOCs in air and water; pesticides in water, fruits, and vegetables; and flavors and off-odors in foods and beverages. The technique was pioneered by Pawliszyn in the early 1990s and has since been commercialized by a number of vendors. The basic principle of SPME is the adsorption of analytes of interest on to a fused silica fiber coated with a porous solid phase that selectively retains the analytes of interest. The SPME device is constructed to enable both extraction and injection and its use involves a number of discrete steps. First, an appropriate SPME fiber is chosen to extract the compounds of interest. Since the SPME device can be regenerated and used for multiple analyses, it is appropriate to first condition the SPME fiber to remove any potential contaminants or carryover. The SPME device is then exposed to the sample for a predefined period of time. The SPME device is removed from the sample and “injected” into the GC, where the elevated temperatures of the GC injector desorb the analyte off the fiber and on to the column.

Continued development of new fiber coatings for SPME will serve to extend the applicability of this technique. Although many vendors of SPME equipment offer application notes describing its use for a particular application, the user should note that development of new SPME methods may require significant effort to determine extraction time, extraction efficiencies, desorption temperature, and other parameters. In most cases, the large ID of the SPME needle necessitates frequent septum replacement. Alternately, a special injection valve designed specifically for SPME injections can be used to obviate the use of septa. The SPME technique is fast, selective, simple, relatively inexpensive, and represents an attractive option over conventional extraction techniques.

2.2 Gas Chromatographs

A wide variety of analytical instrument companies market gas chromatographs. Technological advances in recent years have focused on the development of a wider variety of injection techniques, columns, and other instrument refinements. In the past, the use of packed columns with their resulting inherently high flow rates of carrier gas often required a specialized interface between the gas chromatograph and mass spectrometer (e.g. jet separator, open-split interface). With the proliferation of standard bore (0.25 mm ID) chromatographic columns with an optimal flow rate of the order of 1 mL/min, the most common interface involves introducing the effluent from the GC directly into the ion source region of the mass spectrometer. As a result, jet separators and other specialized GC/MS interfaces have become less important for many analyses. These topics are detailed in various texts and are not discussed further here.

2.2.1 Injectors

Choosing among the various injection techniques requires knowledge of the type of sample, the analytes of interest, their concentrations, and the application. The three major GC injection techniques are split, splitless, and on-column. The most common type of GC injector is the split/splitless, with which both split and splitless injections are possible. These injection techniques are illustrated in Figure 2. The split technique involves the injection of the sample on to the injector with the split valve held in the on position. This places only a fraction of the sample on to the column, with that fraction defined by the ratio of the flow on to the column divided by the flow out the split vent. The splitless technique is similar to the split technique, with the exception being that the split valve is programmed to be in the off position for the approximately 30 s it typically takes for the sample to be flushed out of the injector and on to the column. The split technique is used for more concentrated samples to dilute the amount of solvent and sample flowing on to the column, whereas the splitless technique is most often employed for trace level analyses.

On-column injection of large volumes (i.e. 100 µL) has received increased attention. One of the attractive features of this technique is that it obviates the requirement for solvent vaporization in the sample workup procedures. The solvent is vaporized in a short section of precolumn and then vented in a split port. In some cases, the injector is held at ambient temperatures during injection and then temperature-programmed to improve the efficiency of solvent removal. A review of large-volume injection techniques is provided by Mol et al.

The recent development of pressure-programming of the carrier gas is of particular importance for GC/MS.
The majority of columns used for GC/MS analyses are based on some combination of divinylbenzene and polysiloxane-based polymer for the stationary phase. Column manufacturers offer a wide array of column stationary phases, lengths, diameters, and film thicknesses. An in-depth review of chromatographic theory, solid supports, liquid phases, and other details is provided elsewhere. This section will briefly describe new developments in column technologies.

One salient development has been specialized low-bleed columns for GC/MS analyses. These columns provide in some cases up to an order of magnitude reduction in column bleed at elevated temperatures. This is illustrated in Figure 3, which plots the reconstructed total ion current (TIC) as a function of time for both a standard column and a new low-bleed DB-5 column. Since detection limits are ultimately related to signal-to-noise ratios, reduction of column bleed is an importance advance that will provide improved performance, especially for analytes eluting at higher temperatures.

Another development is new porous layer open tubular (PLOT) columns. These columns have a solid-support stationary phase bonded on to the walls of the column. The separation process is effected by partitioning or by adsorption of analytes on to this stationary phase. These columns are particularly effective for separating highly volatile, low-boiling compounds such as permanent gases, low-molecular-weight hydrocarbons, and halocarbons. As most of these columns still have a minimum ID of 0.53 mm, the resulting large carrier-gas flows may require the use of an open-split interface or a jet separator interface between the gas chromatograph and the mass spectrometer.

Figure 3 TICs showing column bleed with conventional and low-bleed columns. (Reproduced from D.R. Di Feo, Jr, 'A Technical Tourniquet for Capillary GC Column Bleed', Todays Chemist at Work, 39-44, (September 1997), by permission of ACS Publications.)

2.2.2 Columns

Since the first reports of high-resolution capillary columns in the 1960s, development of new column technology has been evolutionary rather than revolutionary.

The majority of columns used for GC/MS analyses are based on some combination of divinylbenzene and polysiloxane-based polymer for the stationary phase. Column manufacturers offer a wide array of column stationary phases, lengths, diameters, and film thicknesses. An in-depth review of chromatographic theory, solid supports, liquid phases, and other details is provided elsewhere. This section will briefly describe new developments in column technologies.

One salient development has been specialized low-bleed columns for GC/MS analyses. These columns provide in some cases up to an order of magnitude reduction in column bleed at elevated temperatures. This is illustrated in Figure 3, which plots the reconstructed total ion current (TIC) as a function of time for both a standard column and a new low-bleed DB-5 column. Since detection limits are ultimately related to signal-to-noise ratios, reduction of column bleed is an importance advance that will provide improved performance, especially for analytes eluting at higher temperatures.

Another development is new porous layer open tubular (PLOT) columns. These columns have a solid-support stationary phase bonded on to the walls of the column. The separation process is effected by partitioning or by adsorption of analytes on to this stationary phase. These columns are particularly effective for separating highly volatile, low-boiling compounds such as permanent gases, low-molecular-weight hydrocarbons, and halocarbons. As most of these columns still have a minimum ID of 0.53 mm, the resulting large carrier-gas flows may require the use of an open-split interface or a jet separator interface between the gas chromatograph and the mass spectrometer.

Figure 3 TICs showing column bleed with conventional and low-bleed columns. (Reproduced from D.R. Di Feo, Jr, 'A Technical Tourniquet for Capillary GC Column Bleed', Todays Chemist at Work, 39-44, (September 1997), by permission of ACS Publications.)

2.2.2 Columns

Since the first reports of high-resolution capillary columns in the 1960s, development of new column technology has been evolutionary rather than revolutionary.
One related development germane to this discussion is that of transfer line GC/MS. This technique was originally demonstrated by Hale and Yost.\(^{27}\) It is based on resistive heating of a short metal-coated column. It has been mainly used for analyses of organics in soil\(^{28}\) and air\(^{29}\).

2.2.3 Fast Gas Chromatography

The field of fast GC is described in several recent reviews.\(^{3,30,31}\) Truly portable gas chromatographs with low power consumption and small footprints have been available for years.\(^{32–34}\) The use of fast GC in conjunction with MS is particularly valuable insofar as it can quickly separate complex mixtures and provide orthogonal information via chromatographic separation in time prior to mass spectrometric detection.\(^{35}\) Successful application of fast GC/MS requires both narrow bandwidth injections and a mass analyzer/data system capable of acquiring data at rates high enough to preserve the information content of the chromatogram. The major impediment to field applications of fast GC/MS involves the inherent difficulties associated with making the mass analyzer and its accompanying vacuum system truly field-portable.\(^{36}\)

2.3 Mass Analyzers

The tremendous versatility of MS is due in a large part to the wide variety of mass analyzers that are available. The different types of mass spectrometers are usually characterized on the basis of what physical property they employ to separate ions of differing \(m/z\). In a time-of-flight (TOF) instrument, ions are separated on the basis of their differing velocities down a flight tube. In a magnetic sector instrument, ions are separated on the basis of their differing curvatures through a magnetic field. In a quadrupole mass spectrometer and a quadrupole ion trap, ions are separated on the basis of their stability in the presence of a radiofrequency (RF) electric field. In Fourier transform ion cyclotron resonance (FTICR) or Fourier transform mass spectrometry (FTMS) instruments, ions are separated on the basis of their differing frequencies of oscillation and the resulting image currents these provide.

The fact that there are so many different types of mass analyzers serves only to strengthen the technique as a whole, as each has its inherent advantages and each has utility for specific applications. Although the term ion trap can be considered to apply to any device that is capable of trapping ions (e.g. quadrupole ion trap, FTICR, or FTMS), the term ion trap will be used exclusively to refer to the quadrupole ion trap from this point forward.

Detection of ions in most mass spectrometers is accomplished through the use of an electron multiplier. This device amplifies the current from an ion beam by a factor as high as \(10^7\). The resulting signal is typically passed through a current-to-voltage converter and then an analog-to-digital converter. Although the resulting signal is represented by the data system as the intensity or abundance, this is an arbitrary unit that has no relation to the actual number of ions detected. For negative-ion mass spectra, a conversion dynode is required to convert negative ions to positive ions prior to detection by the electron multiplier.

Quadrupole and ion trap mass spectrometers comprise more than 75% of all mass spectrometers sold. This percentage is certainly higher if the group is further limited to only GC/MS instruments, most likely because these particular mass analyzers provide the best combination of sensitivity, performance, size, and ease of use.\(^{3}\) Hence, although GC used in conjunction with dual-sector mass spectrometers and FTMS instruments provides the high mass resolution required for certain applications, such applications are far from routine and the discussion here will be limited to the unit mass resolution GC/MS instruments.

Quadrupole mass analyzers offer the primary advantage of ruggedness and ease of use. Although they are relatively free from the ion/molecule problems associated with ion traps, they are not capable of implementing MS/MS experiments, and switching from EI to CI mode requires changing of the ion volumes used in the source. Ion traps are capable of performing both EI and CI experiments without requiring changes in source hardware (in internal source-type instruments only), and can implement MS/MS and MS\(^n\) (\(n\) stages of mass spectrometry) scan modes. It should be noted that CI experiments in an ion trap typically require much lower pressures of reagent gas than conventional beam-type mass spectrometers (i.e. 0.001 Pa versus 10–100 Pa). Negative CI experiments on an ion trap require the use of an external ion source, as electrons do not have a sufficiently long residence time to permit electron capture to occur in the trap. The implementation of MS experiments in a ion trap instrument is more a function of time than space, insofar as a quadrupole mass analyzer has separate regions for ionization, mass analysis, and detection, whereas each of these steps is performed in a distinct time slice in an ion trap. This has some important implications with respect to ion/molecule reactions, in that under certain conditions and given sufficient time, an ion can undergo charge exchange (CE) with neutral species in the ion trap. This can lead to protonation of analyte ions by fragment ions (which typically occurs under space charge conditions), unexpected ions, and erroneous library search results. These effects have been well studied and should provide minimal problems given proper selection of experimental parameters.\(^{37}\)
With respect to sensitivity, there are relatively minor differences between the detection limits of various mass spectrometers used in GC/MS instruments. While vendors continually tout their own instruments as the most sensitive, it is often difficult to compare the performance of different mass analyzers when the vendors use different compounds for assessing their sensitivity and developing their specifications (e.g., methyl stearate, hexachlorobenzene, decafluorobenzophenone). Selectivity can be enhanced through the use of selective ionization techniques and/or more specific MS scan modes. Many mass spectrometers are now available in benchtop size and costs continue to decrease. Not surprisingly, it is the features of the mass spectrometer that often play a more important role in choosing an appropriate GC/MS instrument.

### 2.3.1 Ionization Modes

The most common ionization modes used in GC/MS analyses are EI, CI, and electron capture–negative chemical ionization (ECNCI). A more detailed discussion of each of these ionization modes is provided elsewhere. Although all of these ionization modes are accessible with the use of an external ionization source for the ion trap, the use of ECNCI is precluded with internal ionization ion traps. It should also be noted that the use of CI in quadrupole and external ion trap instruments often requires switching to a “closed” ion volume to enable higher CI reagent gas pressures. In some applications, the user should consider different ionization modes and even different CI reagent gases to improve the selectivity of the analysis. The following section discusses each of these ionization modes, how they affect the types and relative intensities of ions in the resulting mass spectra, and their advantages and disadvantages for GC/MS applications.

**EI is the most common ionization mode.** The reactions involved are shown in Scheme 1.

\[
\begin{align*}
M + e^- &\rightarrow M^{++} + 2e^- \quad \text{Ionization} \\
M^{++} &\rightarrow M^+ \quad \text{Formation of molecular ion} \\
M^+ &\rightarrow A^+ + B^- \quad \text{Decomposition of molecular ion to form ion and radical} \\
M^{++} &\rightarrow C^+ + D \quad \text{Decomposition of molecular ion to form ion and neutral loss}
\end{align*}
\]

**Scheme 1** Reactions associated with EI.

EI typically employs 70 eV electrons to “knock” an electron off a sample molecule M and create the M^{++} ion. This process results in an ion population with a distribution of energies which can subsequently undergo collisional or vibrational deactivation to form a molecular ion M^{++}, fragmentation to form the ion A^+ and radical B^-, or rearrangement to form the ion C^+ with a neutral loss of molecule D. The result is a mass spectrum that includes a wide range of fragment ions that can serve as a “fingerprint” for that compound. This is illustrated in Figure 4(a), which shows an EI mass spectrum of α-pinene, a common monoterpene. Although EI is perhaps the simplest and easiest ionization mode to implement, it “spreads” the signal from a compound over a large number of fragment ions, which may result in diminished precursor ion counts and hence reduced sensitivity for MS/MS applications.

CI is the next most common ionization technique. In the broadest sense, CI encompasses a range of techniques based on ion molecule reactions, including positive chemical ionization (PCI), ECNCI, and CE, but the term is most often used to refer to the most common form of CI which is PCI. CI is typically employed to provide an increased molecular ion signal from which a compound’s molecular weight may be deduced. An illustration of the major reactions associated with the use of methane as a CI reagent gas is shown in Scheme 2.

\[
\begin{align*}
\text{CH}_4 + e^- &\rightarrow \text{CH}_4^+ + 2e^- \quad \text{Electron ionization of reagent gas} \\
\text{CH}_4^+ + \text{CH}_4 &\rightarrow \text{CH}_5^+ + \text{CH}_4^- \quad \text{Ion/molecule reaction to produce reagent gas ion} \\
M + \text{CH}_4^+ &\rightarrow \text{MH}^+ + \text{CH}_4 \quad \text{Transfer of proton from reagent gas ion to sample molecule}
\end{align*}
\]

**Scheme 2** Reactions associated with CI.

If the pressure of the methane reagent gas is significantly greater than that of the sample molecule M, methane is preferentially ionized by an EI process to form the ion CH_4^+. This cation then undergoes a proton transfer reaction with a neutral methane molecule to produce the reagent ion CH_5^+, which in turn undergoes another proton transfer reaction with the sample molecule M to form a protonated molecule MH^+.

The exothermicity of this last reaction is governed by the difference in proton affinity (PA) between the reagent gas and sample molecule. If the PA of the sample molecule is less than that of the reagent gas, ionization will not take place. Selecting reagent gases with increasingly larger PAs than the sample molecule will increase the extent of fragmentation in the resulting mass spectra. These features are often exploited to selectively ionize and control the amount of energy imparted in the sample molecule and hence fragmentation in the resulting mass spectrum. This is illustrated in Figures 4(b) and 4(c), which show the methane and acetonitrile CI mass spectra of α-pinene. In the case of acetonitrile CI, the difference in PAs is smaller than with methane CI, with a much more intense MH^+ ion at m/z 137 and a simpler mass spectrum.

Most routine applications of CI typically involve the use of methane as a reagent gas, which has a PA low
enough to protonate nearly any organic compound. Many applications take advantage of differing PAs of the components in a mixture by using a reagent gas with a PA higher than methane to provide more selective ionization of analytes in question. The use of CI in conjunction with MS/MS is quite common, since MS/MS often requires a large molecular ion signal for subsequent isolation and fragmentation. Here, the reagent gas is chosen to concentrate the signal for a sample into fewer ions and provide a larger initial precursor ion count for a subsequent MS/MS experiment. The most common reagent gases in order of increasing PA include methane, isobutane, water, methanol, acetonitrile, and ammonia. More extensive tabulations of PAs of various reagent gases are provided elsewhere.\(^{38}\)

In ECNCI, a negatively charged molecular ion is formed when a sample molecule captures an electron. These electrons can be generated thermally from a filament or produced as a by-product of gas-phase ion/molecule reactions. Since electrons formed inside an ion trap are rapidly ejected by the RF field, the use of this ionization technique necessitates an external ionization source for the ion trap. Given that rate constants for electron capture are typically two orders of magnitude greater than those for ion/molecule reactions, ECNCI is inherently more sensitive than conventional CI techniques. ECNCI is particularly well suited for organic compounds containing halogen atoms, nitro groups, and aromatic rings.

### 2.3.2 Scan Modes

Given the wide variety of mass analyzers and scan modes, it is often difficult for the novice to understand the implementation and fragmentation pathways followed in specific MS experiments. Lehman\(^{39}\) and Kondrat\(^{40}\) provide useful pictograms for representing such information. Nearly all mass analyzers allow the user several scan modes to choose from. These range from the relatively nonspecific MS and SIM modes to the more selective tandem MS (MS/MS, MS/MS/MS, and MS\(^n\)) modes. In the case of tandem quadrupole mass spectrometers, all three MS/MS scan modes are accessible. This includes product-ion, parent-ion, and neutral-loss scans. In the case of quadrupole ion traps, only product-ion scan modes are accessible in commercial instruments. This

![Figure 4](image_url)

(a) EI, (b) methane CI, and (c) acetonitrile CI mass spectra of \(\alpha\)-pinene.
section discusses each of these scan modes and their use in GC/MS applications.

Mass spectrometers are most commonly operated in conventional MS scan mode, in which the mass analyzer is set to acquire a mass spectrum across a user-specified range of m/z values. MS mode is typically used when attempting to obtain sample spectra for subsequent library searching and tentative identification. SIM mode involves setting the mass analyzer to acquire intensity data across specific m/z value(s). It is most commonly used in conjunction with GC/MS to improve detection limits for specific target compounds and the resulting plot of the intensity of that selected ion as a function of time is referred to as a SIM mass chromatogram. As a more definitive identification of a particular compound typically requires the presence of more than one characteristic m/z value for that compound, a SIM application may require monitoring of more than one ion. On GC/tandem quadrupole MS instruments, parent and neutral-loss scan modes are useful when screening for particular target compound classes. Hunt and Shabanowitz[41] provide an excellent summary of the use of MS/MS scan modes to identify specific target compounds.

The proliferation of relatively low cost GC/MS instruments based on the use of ion trap mass analyzers with the MS/MS capability has been shown to be useful for a variety of mixture analysis problems. In these applications, the selectivity of MS/MS is used in conjunction with GC to simplify target compound analysis. MS/MS involves isolation and storage of a specific precursor ion, fragmentation of that ion via collision-induced dissociation (CID), and acquisition of a mass spectrum of the product ions. The ion trap enables additional flexibility in the ways in which isolation and CID can be performed. Isolation techniques include apex, consecutive or two-step, and broadband techniques such as random noise and SWIFT (stored waveform inverse Fourier transform).[42–46] CID techniques can be achieved via single frequencies (resonant excitation) and broadband techniques (nonresonant excitation).[47–50] In contrast to conventional tandem mass spectrometers which require a separate mass analyzer for each stage of MS (tandem-in-space), the ion trap can perform ionization, isolation, CID, and mass analysis within one analyzer (tandem-in-time). This means that the ion trap can be used to perform two (MS/MS), three (MS/MS/MS), and unlimited (MS^n) stages of MS. In practice, two stages of MS usually suffice for selective identification of a target compound. Although parent and neutral-loss scan modes have been demonstrated on an ion trap, they have yet to be implemented on any commercial ion trap instruments.

The primary reason to use an MS/MS scan mode in GC/MS analyses is that it simplifies the resulting chromatogram for subsequent target compound analysis. Detection limits in MS/MS scan mode are usually better than MS due to reduced noise levels. They may not be as low as SIM as the CID process in an MS/MS experiment may not result in 100% conversion of a precursor ion to a product ion, especially for highly conjugated ions. However, MS/MS is a much more reliable means for target compound identification and quantitation, as a precursor–product ion combination is inherently more characteristic of a particular compound than a single ion from either MS or SIM modes. MS/MS is not a panacea for each and every target compound. Lightweight compounds, such as CH₄ and NO₂, produce few fragment ions and hence cannot be monitored via MS/MS. Structural isomers, such as xylenes and monoterpenes, produce nearly identical MS/MS spectra and hence cannot be differentiated from one another unless prior chromatographic separation is achieved. These cases, however, are the exceptions, and MS/MS is becoming more widely accepted for selective monitoring of target compounds in complex mixtures.

2.3.3 Field-portable Mass Spectrometers

The development of field-portable GC/MS instrumentation is receiving increased attention. The driving force behind this is the ever-growing number of applications requiring rapid, in situ monitoring by instrumentation with minimal space, weight, and power requirements. Several companies have developed and marketed small gas chromatographs and these instruments have been used widely for years. The use of fast GC implies smaller diameter columns and reduced sample capacities, and in some cases this may result in poorer detection limits. Fast GC also results in peaks that are very narrow as measured on the chromatographic timescale, and hence necessitates a detector with a very fast response time, or, in the case of an MS detector, fast scanning speeds. Only a few companies have developed field-portable MS and GC/MS instruments. Bruker’s Mobile Environmental Mass Spectrometer can be equipped with a number of sampling modules for air, water, and soil analysis.[51–55] While this system has a proven ability for on-site analysis, it is mobile rather than truly portable. More recently, efforts have focused on developing smaller instrumentation that can be carried into the field on a truck or ported to a site by one or more individuals; and a human-portable quadrupole-based GC/MS system has been developed.[56–58] Other groups have developed miniaturized sector[59] TOF,[60,61] and ion cyclotron resonance-type mass spectrometers.[62,63] Recent reviews discuss requirements for field-deployable monitors[64] and detailed specifications for commercial field-portable GC and GC/MS instruments.[65]
3 DATA ANALYSIS

GC/MS instruments usually come equipped with data systems provided by the manufacturer. Usually, this is done so as to enable both instrument control and data analysis. Since instrument control routines are obviously specific to each instrument, they are not discussed further here other than to mention that data systems increasingly automate more routine tasks such as “smart” autotuning and diagnostics. Instrument manufacturers have been repeatedly urged by users to integrate routines into their data systems to enable GC/MS data to be saved in the JCAMP-DX (Joint Committee on Atomic and Molecular Physics–Data eXchange) format that is becoming the standard format to facilitate data interchange. Other non-instrument-specific data systems have been developed for the sole purpose of data analysis. These data systems may include enhanced features such as library search routines, and chemical structures for each compound in the library. They are useful in larger MS laboratories insofar as they free the user from having to learn and utilize the different data systems associated with each instrument.

One of the most common GC/MS data analysis procedures involves library searching of experimental mass spectra against reference or library spectra. In the past, instrument manufacturers integrated such routines into their data systems using their own libraries and search routines. More recently, both vendors and users have begun to standardize on the use of mass spectral libraries and search routines provided by the National Institute of Standards and Technology (NIST). NIST continues to add new spectra to their library, performs quality control and oversight over new and existing data, and has continually improved the algorithms for library searching. At the most recent count, the NIST mass spectral library contained more than 129,000 EI mass spectra of over 107,000 different compounds. The NIST library now represents the most widely used mass spectral library in the world. The NIST search software also includes tools for deconvoluting GC/MS data, mass spectral interpretation, and chemical substructure identification.

In recent years, more attention has been paid to developing and formalizing good laboratory practices (GLPs) as related to the application of MS. A recent report by Boyd et al. discusses efforts towards standardization of instruments, quality assurance/quality control (QA/QC) procedures, and performance requirements and is very worthwhile reading for any practitioner of GC/MS. \(^{(66)}\) Another worthwhile report by Baldwin et al. discusses criteria for identification, quantitation, and determining detection limits. \(^{(67)}\)

3.1 Identification

Mass spectral libraries used in target compound analyses may be larger, more comprehensive libraries such as the NIST library or smaller, more customized libraries used for specific applications. The former are typically encoded into electronic format and are available from NIST, Wiley/NBS (National Bureau of Standards), \(^{(68)}\) and EPA/NIH (Environmental Protection Agency/National Institute of Health) \(^{(69)}\) (note that these last two have been largely supplanted by the NIST library). The latter include specialized compilations of mass spectra in hardcopy form of various compound classes including steroids; \(^{(70)}\) oil components; \(^{(71)}\) pollutants, pesticides, and metabolites; \(^{(72)}\) environmental contaminants; \(^{(73)}\) drugs; \(^{(74)}\) priority pollutants; \(^{(75)}\) and ECNI spectra. \(^{(76)}\)

Commercially available data systems use one of two basic search algorithms in computing the degree of similarity between experimental and library spectra. These are the dot-product metric (used in Finnigan and Varian data systems) and the probability metric used in the probability-based matching (PBM) system (used in Hewlett-Packard data systems). The search can be bounded by various constraints, such as molecular weight and elemental composition. The result of the search is a ranked list which includes some metric to describe the degree of match between experimental and library spectra. Various library search algorithms utilize a number of data-system-specific terms to describe this degree of match. The “match factor” (used in NIST library search software) or “purity” metric (used in Finnigan and Varian data systems) attempts to take into account the degree of match between the experimental and library spectra. This metric is computed by a dot-product of a peak-by-peak comparison of the two spectra. The “reverse match factor” (NIST library search software) or “fit” metric (used in Finnigan and Varian data systems) attempts to fit the library spectrum into the experimental mass spectrum. Peaks that are in the experimental spectrum but are not in the library spectrum are disregarded in evaluating the degree of match. This type of search has the advantage of being able to determine multiple components in an experimental spectrum and/or to disregard any contaminant or background peaks in the sample spectrum. An “rfit” or “reverse fit” (used in Finnigan and Varian data systems) attempts to fit the experimental mass spectrum into the library spectrum. Given the confusing terminology and different means by which various algorithms compute the degree of match, users are urged to consult the documentation for their data system for more detailed information as to how this is achieved.

The result of a library search is no more than a ranked list of the most similar library mass spectra.
Sparkman has summarized the use and misuse of library searching and users are reminded that a library search is meant to assist the user in identification and that the top ranking hit is not necessarily proof positive of the identification. Erroneous results may be due to errors in the experimental mass spectrum, errors in the reference mass spectra, or the simple fact that the library does not contain that spectrum.

USEPA criteria for positive identification of a target compound usually call for a retention time match with a known standard as well as simultaneous maximization of three major ions for that compound within a specified time window. More commonly, data systems are configured to identify a target compound on the basis of both a retention time match and a library search match above a certain preset match factor. It should be noted that recent development of retention time locking software minimizes drift of retention times due to instrument or parameter modifications. When the mass spectrometer is operated in SIM mode, positive identification requires both retention time match as well as the presence of one or more quantitation or “quan” ions within a specific time window. For operation in MS/MS mode, the USEPA has yet to develop formal criteria for positive identification of target compounds via GC/MS/MS. Although the American Society for Mass Spectrometry’s (ASMS) workshops have discussed this issue, the selection of a suitable precursor–product ion combination is left to the user.

3.2 Quantitation

External standards are most often used for quantitation of a limited number of samples. Here, working standards of the target compounds are prepared from appropriate sources (e.g., pure liquids, dilute stock solutions, or gas standards). These standards are analyzed under the same conditions as the samples. The quan ion is chosen to reflect an ion that has high abundance and, in the cases of potential interference, is selective for that compound. A calibration curve representing the quan ion intensity versus concentration is constructed and used to compute concentrations in the samples.

Internal standards are used to account for short-term drift in instrument response in quantitation. The process is the same as with external standards except that standards and samples are “doped” with a constant amount of a carefully selected internal standard. The calibration curve therefore plots the ratio of quan ion intensity for the target compound to the quan ion intensity for the internal standard. To determine the concentrations of large numbers of target compounds in a single analysis, several internal standards may be employed to more accurately reflect the different chromatographic behaviors of the target compounds. For the most accurate quantitation, the internal standard is an isotopically labeled form of the analyte in question. This means of quantitation is usually referred to as an isotopic dilution method. In this case, the internal standard behaves almost identically to the target compound, will elute at nearly the same retention time, and will account for any analyte losses during sample preparation.

The use of powerful quantitation software in modern GC/MS data systems can greatly facilitate and automate the identification and quantitation processes. This software typically has a steep learning curve associated with it, requires time to enter parameters for searching and quantitation, and hence is typically applied in routine, high-volume analyses. Despite the power of automated identification and quantitation software, misinterpretation of data can sometimes occur and users should remember that these routines do not remove the need for proper review of the data and results.

3.3 Pattern Recognition, Neural Nets, and Artificial Intelligence Methods

The “heyday” of the development of techniques based on artificial intelligence (AI) for automated mass spectral interpretation is past. Over-zealous predictions of expert system and AI methods have yet to meet user expectations. Although both the Dendral Project and the Self-training Interpretive and Retrieval System (STIRS) have demonstrated their utility for structure elucidation from MS data, these software tools never enjoyed wide acceptance by users. Nevertheless, a wide variety of multivariate data analysis, pattern recognition, and neural network software continue to show their utility in diagnosing problems with GC, correcting for mass spectral drift and dealing with the large amount of information contained in GC/MS data. The use of such techniques for GC/MS data analysis continues to evolve, and advances are slowly being incorporated into data systems.

4 PRACTICAL CONSIDERATIONS

As with any analytical technique, the most useful teaching method for learning the many and sundry details associated with the practice of GC/MS is hands-on experience. The purpose of this section is to briefly touch upon some of the more important considerations associated with optimizing both the gas chromatograph and mass spectrometer to obtain the desired results.
4.1 Gas Chromatography

Of critical importance for GC/MS analyses is developing the appropriate chromatographic conditions to achieve the desired separation. This job is made easier by the wide range of stationary phases, column lengths, IDs, and film thicknesses now available. A quick perusal of any chromatography catalog shows a wealth of information regarding the various options for analysis of specific compounds of interest for an incredibly wide variety of applications. Once the column is selected, the user must then decide upon a temperature program and carrier gas flow rate. For highly volatile species, subambient GC temperatures may be required to effect separation of low-boiling compounds or alternately a longer column can be chosen. For more polar species, some chromatographic columns have higher upper temperature limits, thus enabling eluting of these higher boiling species. Rather than using best guess or trial and error methods for deciding upon appropriate parameters for a GC separation, the user can employ modeling, neural network, or simplex software to optimize conditions.

In the past, most GC columns had sufficiently large IDs that they provided gas flows that were too large for direct coupling to a mass spectrometer. Hence, devices such as open-split interfaces, jet separators, and even membrane separators were employed to reduce the gas flows and in some cases provide an extra enrichment step prior to introduction into the source region of the mass analyzer. These devices are rapidly becoming obsolete, as manufacturers devise mass analyzers and/or pumping systems that are more forgiving of the wide range of gas flows from microbore (<0.25 mm ID), standard bore (0.25 mm ID), and megabore (0.53 mm ID) columns.

Furthermore, users are becoming more familiar with simple techniques to provide easier switching of columns. Rather than connecting the end of a column directly to the source region of the mass spectrometer, many users use a short section of deactivated fused silica transfer line between the column and mass analyzer. This practice means that the user does not need to vent the mass spectrometer when changing columns, which saves both time and effort. But it also necessitates a means for connecting the column to the transfer line. Past practice here was to use low-dead-volume stainless steel fittings with appropriate ferrules. These devices were difficult to connect properly, heavy enough to place stress on the column and transfer line, and required sufficient experience to adequately judge when the nuts were sufficiently tightened to minimize leaks. Polymide-coated glass press-fit connectors are a much better option for these connections, since they are easy to use, lightweight, and provide an excellent leak-tight seal so long as the column is cut properly and inserted correctly.

4.2 Mass Spectrometry

One of the most problematic aspects involved with the practice of GC/MS is the fact that the instrument requires a vacuum system. A surprising feature of many GC/MS instruments is that they do not include a pressure sensor or do not even permit one to be attached to the vacuum manifold without substantial modifications. The operating pressure of the mass spectrometer is a critical piece of information that is highly useful in gauging the status of the instrument. With a quick glance at the pressure, the user can determine whether the system is operating nominally or if pressures are excessive. Although the pressure can sometimes be inferred from the instrument’s diagnostic routines (i.e. turbo pump speed, which is usually expressed as a percentage of normal operating speed), this is certainly no substitute for an actual pressure readout. For users purchasing a GC/MS system, it is highly recommended that the instrument be configured with some sort of pressure gauge.

Leak detection remains as one of the more problematic aspects to operating a GC/MS instrument. In performing any maintenance or service to the mass analyzer, the user runs the risk of inducing a leak into the vacuum system and hence either reducing the performance of the instrument or preventing its operation. If the leak is minor enough so that the instrument can be operated without risk of damage to the filament and multiplier, the mass spectrometer itself can be used as a leak detector. Here, the user would direct a stream of argon or some other low-molecular-weight hydrochlorofluorocarbon (HCFC) at suspected leak sites while concomitantly observing the mass spectral response at the appropriate m/z range.

In an ion trap instrument, the relative ratios of air/water peaks can be used to deduce the presence of either excessive water levels or air leaks. Here, reactions between ions and neutrals are the cause of the observed response. When there are high water levels in the ion trap, the reactions shown in Scheme 3 occur.

\[
\text{H}_2\text{O} + e^- \rightarrow \text{H}_2\text{O}^+ + 2e^- \quad \text{El process resulting in formation of } m/z \text{ 18}
\]

\[
\text{H}_2\text{O}^+ + \text{H}_2\text{O} \rightarrow \text{H}_3\text{O}^+ + \text{HO}^- \quad \text{Ion molecule reaction resulting in formation of } m/z \text{ 19}
\]

**Scheme 3** Production of water ions in an ion trap.

Hence, the large intensity ratios of m/z 19 (H$_2$O$^+$) to 18 (H$_2$O$^+$) indicate excessive water levels in the trap. When air levels are nominal, the ratio of m/z 28 (N$_2$^+) to 32 (O$_2$^+) is usually approximately 3 to 1. Large levels of nitrogen contamination in the carrier gas are indicated by higher ratios of m/z 28 to 32. When there is significant air in the ion trap, the reactions shown in Scheme 4 occur.
N₂ + e⁻ → N₂⁺ + 2e⁻ \text{EI process resulting in formation of } m/z 28

N₂⁺ + O₂ → N₂ + O₂⁺ \text{Charge exchange process resulting in formation of } m/z 32

Scheme 4 Production of air ions in an ion trap.

Large intensities of \( m/z \) 32 relative to 28 indicate the presence of a minor air leak. The presence of a broad peak centered around \( m/z \) 32 indicates the presence of a major air leak. The reason in both cases is that the energetics of the CE process favor oxygen molecules retaining the bulk of the charge under multiple collision conditions.\(^{38}\)

Deducing the source of a major leak is often problematic. Although it is hoped that the source of such a leak could be deduced by sound or by rechecking the connections associated with the last modifications done to the system, this does not work in all cases. Such problems are best approached systematically, with the user working backwards from the instrument, checking that the pumps are in working order, and checking all connections to the vacuum manifold, and the connections between the column and the transfer line to the mass spectrometer.

Chemical background is also of concern for trace level analyses. This background can be due to septum bleed, column bleed, pump oil, and trace contaminants in the carrier gas stream. The user must pay close attention to choosing the appropriate quality components to provide the background levels necessary for the analysis in question. The use of silico-grade steel in the manufacturing of mass spectrometer components has been shown to provide reduced background levels as well as facilitating analyses of more polar species.

GC/MS instruments increasingly come equipped with powerful diagnostic routines to check the performance of individual components. Users can use these to debug problems and trace them to specific sources, whether it is a power supply, specific printed circuit board, or component. These instruments also come equipped with autotune procedures that automate processes such as multiplier gain check, mass calibration, and other common operations. Although the user should take full advantage of these in day-to-day operations, they are no substitute for proper evaluation of instrument performance by a human expert. USEPA procedures commonly call for the instrument to be tuned daily if necessary to ensure that EI mass spectra of bromofluorobenzene or some other reference compound meet predefined performance criteria. As a final suggestion, users are urged to maintain a logbook to document instrument use, performance, and maintenance procedures such as oil changes.

5 PERSPECTIVE AND FUTURE DEVELOPMENTS

The future of GC/MS should see further progress in improvement of GC performance (i.e. faster elutions, lower bleed columns, wider variety of columns), MS performance (i.e. lower detection limits, wider mass ranges, faster scanning speeds), data systems (totally automated tuning, analysis, interpretation and quantitation), and further miniaturization for specialized field applications. Ion traps will most likely be the mass analyzer of choice for GC/MS and GC/MS/MS applications due to their numerous high-performance features.\(^{89,90}\) The ion trap is small, relatively simple, and inexpensive. It is recognized as one of the most sensitive mass spectrometers currently available. It has excellent experimental versatility and is capable of collecting EI, CI, and MS/MS data. This tandem MS capability is particularly valuable for targeted compound analysis, in which additional stages of MS can be used to tailor the selectivity of the analysis to the compound and matrix of interest. High mass analysis,\(^{91,92}\) high mass resolution,\(^{93}\) and even the Fourier transform technique have been demonstrated on an ion trap.\(^{94,95}\) Recent work shows that the ion trap can be operated using air instead of helium as a buffer gas while maintaining unit mass resolution up to \( m/z \) 200.\(^{96}\) It remains in the hands of instrument manufacturers to incorporate these advances into commercial GC/MS instruments. Collectively, these features make the ion trap well suited for a host of applications and the future should see ion traps gradually replacing quadrupole mass analyzers in these applications.

Although MS/MS and its utility for target compound analysis and structure elucidation has been known for years, it has only recently been exploited on a more routine basis in conjunction with GC. Some of the limiting factors in this have been the high cost of tandem MS instruments and the lack of progress in the development of computerized databases of MS/MS spectra. Although there have been some efforts in this area,\(^{97,98}\) the problems associated with differing MS/MS spectra from different instruments and the dependence of such spectra on operating conditions (e.g. CID gas pressure, collision energy, etc.),\(^{99,100}\) and the lack of further championing of such efforts by an organization such as NIST, have hampered efforts in this area. If a user wants to employ MS/MS for target compound analysis, there is no database or tabulated information on precursor–product ion combinations. Although such information can in some cases be gleaned from the literature,\(^{41}\) more often the user must evaluate a compound’s fragmentation patterns. The continued development and eventual acceptance of MS/MS as a technique will require the development of an MS/MS database.
But without question, data systems represent the greatest area for progress. The improvements in data system abilities to facilitate instrument control and data analysis has been a major reason behind the acceptance of MS as a more routine detector for GC, especially in the hands of nonexperts. Future instruments should provide even more powerful software for “autotuning”, data interpretation, and diagnostics. Finally, “smart” selection of parameters for MS/MS experiments (i.e. selecting precursor–product ion combinations, tuning for precursor ion selection and CID processes) will enhance the utility of GC/MS/MS experiments. These advancements will continue to promote an even wider acceptance and use of GC/MS in the future.

1 INTRODUCTION

1.1 Definitions of Resolving Power and Resolution

The RP of a mass spectrometer is a measure of the ability of the instrument to separate ions of closely similar mass-to-charge ratio, \( m/z \), and to produce a spectrum of a given resolution. Because it is somewhat subjective to decide whether or not two overlapping peaks are just resolved, several different definitions of RP have been suggested and it is useful to consider three of the most commonly used.

The RP of magnetic deflection instruments is usually expressed in terms of the “10% valley” definition or the “5% adjacent peak contribution” definition which are equivalent. In such an instrument operated with narrow source and collector slits, peaks are triangular. They are arbitrarily said to be just resolved either when the valley between two peaks of equal height is 10% of the height of the peaks or when each peak contributes 5% of the peak height to the valley between the peaks, as shown in Figure 1.

The above definition is rarely used as a measure of the RP of other types of mass spectrometer since the peak shapes they produce are often closer to Lorentzian rather than triangular. The full width at half maximum (FWHM) definition is used. This is given by the mass of the ion, \( m \), giving rise to the peak, divided by the full width of the peak in mass units at half the maximum height of the peak, \( 1/m \). Defined in this way, the RP \( m/\Delta m \)
is approximately twice that based on the 10% valley definition. The FWHM definition has the advantage that it is largely independent of peak shape and it can be measured even when the baseline is noisy as a result of unresolved low intensity peaks arising from “chemical noise”.

The terms “low resolution” and “high resolution” are somewhat subjective but low-resolution spectra are usually those obtained under conditions such that unit mass resolution is obtained up to about $m/z$ 2500. Quadrupole instruments are unusual in that they are normally operated at unit mass RP, i.e. an RP of 500 at $m/z$ 500, 1500 at $m/z$ 1500, and so on. Since their upper limit for transmission of ions is about $m/z$ 3000–4000, however, they are intrinsically low-RP instruments.

High-resolution spectra are usually obtained at an RP sufficiently high to resolve at least lower mass isobaric ions so that the masses of the components may be accurately measured. In some circumstances, therefore, a spectrum obtained at a resolution of 2000 may be considered a high-resolution spectrum for low mass species, but for high mass biological samples an RP in excess of 10 000 may be needed to solve a specific problem.

1.2 Need for High-resolving Power

At all but the lowest masses, there are often several ions of different isotopic composition that have the same nominal mass; these are known as isobaric ions. At low-RP, peaks due to isobaric ions are not resolved, so that the recorded peak is made up of contributions from two or more ionic species. If it is assumed that the peak is due only to one component and an attempt is made to measure the accurate mass of the ion giving rise to the peak, a weighted average that does not correspond to the mass of any single isotopic composition is obtained. Hence for accurate mass determinations, it is essential to work at an RP that separates all likely isobaric ions so that the measurement may be carried out on a peak due to a single component. For example, even at a nominal mass of 28 Da, isobaric ions commonly found are CO$^+$, N$_2$ and C$_2$H$_4$, the accurate masses of which are 27.9949, 28.0061 and 28.031 Da, respectively. The difference in mass, $\Delta m$, between CO$^+$ and N$_2$ is 0.0112 Da, so that the RP required to separate them is $28/(0.0112)$ or 2500. At higher masses, there are many more possible isobaric ions, but, in general, only a few are likely to be present in a given sample and so to interfere with the ion of interest. It is usual to work with an RP just sufficient to separate ions that may cause interference since working at a higher RP normally reduces sensitivity. At masses greater than about 500 Da, it becomes increasingly difficult to separate all possible isobaric ions, but, in practice, relatively few contaminants are likely to be present, so that an RP of 10 000–20 000 is often adequate. For very complex systems, however, an RP of several hundred thousand may be necessary in order to ensure that the peak of interest is resolved. An example of a high-resolution electrospray ionization (ESI) spectrum of the B protein of methane monoxygenase is illustrated in Figure 2. This shows overlapping sets of isotope peaks of two multiply charged ions which in a simple quadrupole instrument would appear as a single peak at $m/z$ 1220.

When the molecular weight of a sample exceeds the RP of a mass spectrometer at that value of $m/z$, it is no longer possible to resolve individual isotope peaks such as those due to the presence of varying numbers of $^{13}$C, $^{15}$N and $^{34}$S isotopes. The mass of
molecular ions derived from measurements on unresolved peaks is therefore the *average* molecular mass rather than the *monoisotopic* molecular mass derived from measurements at high RP. It is important to make this distinction since for high-mass biological samples, the difference between these two masses may be several daltons. It is also important to note that the mass of the monoisotopic peak is significantly higher than the nominal mass for such samples because of the high number of hydrogen atoms present (H = 1.007825). For example, the nominal molecular mass of human insulin is 5802 Da, the monoisotopic molecular mass is 5804.6 Da, and the average mass is 5808.6 Da. Another example of this is illustrated in Figure 3. A particular problem for which high RP is essential is the study of the incorporation of deuterium atoms by H/D exchange into proteins. If, for example, a protein of molecular weight 50000 Da incorporates a single deuterium atom, thereby increasing its molecular weight by 1 Da, a RP of 50000 is required to resolve the peaks of the deuterated and undeuterated ions even if the ion is multiply charged as in ESI. In general, the number of hydrogen atoms that exchange varies, so that a series of peaks results and their resolution requires an RP equal to the molecular weight of the protein. In the ESI spectra of many proteins, the many possible isotope peaks are not resolved in a low-resolution spectrum because if the ions carry \( n \) charges, the peaks are separated by only \( 1/n \) of a unit on the \( m/z \) scale. This is discussed more fully in a later section.

2 INSTRUMENTATION

2.1 Magnetic Deflection Instruments

Ions of mass-to-charge ratio \( m/z \), where \( z \) is the number of electronic charges \( e \), when subjected to an accelerating voltage \( V \) acquire a velocity \( v \), where

\[
Vze = \frac{mv^2}{2}
\]  

When they enter a magnetic field of strength \( B \) perpendicular to the direction of the ion beam, the ions describe a circular path of radius \( r \) such that

\[
Bzev = \frac{mv^2}{r}
\text{ or } r = \frac{mv}{Bze}
\]  

For a constant value of \( B \), the radius described is therefore proportional to the momentum of the ions. Combining Equations (1) and (2) gives the normal Equation (3) for a magnetic deflection instrument:

\[
\frac{m}{z} = \frac{B^2r^2e}{2V}
\]  

In practice, whichever ionization method is employed, a beam of ions emanating from the source slit in the \( xz \) plane which have a range of energies also have an angular divergence in the \( y \) direction, normally given the value of \( 2\alpha \) at the source slit. A magnetic sector is described as “single focusing” because it focuses a monoenergetic beam of ions of a given mass diverging from the source slit and so gives “direction focusing”. It does not, however, focus ions at a given point if they have different energies (i.e. velocities), so it does not provide “velocity focusing” and its RP is therefore reduced. High-resolution magnetic sector instruments employ an electric sector to reduce the energy spread because it brings to focus a diverging monoenergetic beam of ions. The focusing properties of magnetic and electric sectors are illustrated in Figure 4. Certain geometrical arrangements of an electric and a magnetic sector are termed “double focusing” in that the energy dispersion of one sector is equal and opposite to that of the other and direction focusing is maintained throughout the instrument. These are usually fitted with variable \( \alpha \)- and \( \beta \)-slits to allow the angular divergence of the beam and the energy bandpass of the instrument to be varied. Two of the most popular geometries are based on variations of those known as the Nier–Johnson(1) and Mattauch–Herzog(2,3) geometries and these have formed the basis of a number of commercial instruments. They are illustrated in Figure 5.

The performance of double-focusing instruments is determined primarily by the size of aberrations from second-order terms that arise from such factors as field inhomogeneities and fringing fields. These aberrations

![Figure 3 Nominal, monoisotopic and average molecular masses. (Adapted by permission of the American Chemical Society, from J. Yergy, D. Heller, R.J. Cotter, C. Fenselau, *Anal. Chem.*, 55, 353 (1983).)](image-url)
are normally reduced by using electrostatic lenses to optimize performance, e.g. hexapole lenses to correct for image rotation and curvature. High RP is maintained, especially if the collector slit length is reduced. In some cases, further improvement in performance has been obtained by the use of non-normal entry into the magnetic sector to provide some focusing in the z direction (the direction of the magnetic field). The use of tapered pole faces that produce small radial field gradients has a focusing action in one plane and divergence in another, but when the magnetic sector is made up of several segments there is an overall focusing effect. This improves the high-mass performance without increasing the size of the

Figure 4 Focusing of ion beams by (a) electric and (b) magnetic sectors. (Reproduced by permission of Academic Press, from Jennings and Dolnikowski.\(^{15}\))

instrument. Such instruments are capable of RPs in excess of 100 000 and until the development of commercial Fourier transform ion cyclotron resonance (FTICR) instruments, double-focusing magnetic deflection instruments provided the highest RP commercially available.\(^{4}\)

Two-sector instruments have been widely used for tandem mass spectrometry work, either in the investigation of products of metastable transitions or of collision-induced decomposition of ions. By making use of a scan of the accelerating voltage \(V\) at constant \(E\) and \(B\) in a

forward geometry instrument (EB), all precursors of a given product ion are observed. Similarly, in a reverse geometry instrument (BE), a scan of E at constant V and B gives a spectrum of all products of a given precursor ion. The release of translational energy in the fragmentation reactions degrades the resolution of such spectra and the RP attainable is often only 100–200. Higher RP of the product ions is obtained by use of the linked scan in which V is held constant and B and E are scanned simultaneously such that the ratio B/E has a constant value determined by the mass of the precursor ion. In a typical 30-cm radius double-focusing instrument, the product ion resolution is about 1000 but the resolution for precursor ion selection is only in the region of 350.\(^{(5)}\)

Higher resolution tandem mass spectra require the use of a multisection instrument such as a four-sector instrument of either EEBE or BEBE geometry.\(^{(6)}\) In principle, both the first and second double-focusing instrument can be operated at high RP, so that both the precursor and product ions can be selected precisely. In practice, one or other of the analyzers is operated at a RP that is just sufficient for the problem under investigation because the sensitivity of the experiment is otherwise very low. Since it is usually the precursor ion that is selected at high RP, hybrid tandem instruments have been used in which the second analyzer is a quadrupole analyzer with an RP of about 1500.\(^{(7)}\)

### 2.2 Quadrupole Mass Analyzer

The quadrupole mass analyzer consists of four parallel rods, separation 2\(r_0\), of hyperbolic cross-section, though properly spaced rods of circular cross-section give a similar performance.\(^{(8)}\) Opposite pairs of rods are connected electrically and a direct current (DC) voltage \(U\) and radiofrequency (RF) voltage \(V_0 \cos(wt)\) are applied to the rods. The transmission characteristics are normally described in terms of the two parameters, \(a\) and \(q\) where, Equations (4–6)

\[
a = \frac{8eU}{m r_0^2 w^2} \\
q = \frac{4eV_0}{m r_0^2 w^2}
\]

so that

\[
a = \frac{2U}{V_0} \frac{q}{q}
\]

For ions of a given \(m/z\), certain values of \(a\) and \(q\) lead to stable oscillations so that these ions are transmitted; all others are lost to the rods or the walls of the vacuum system. This is illustrated in Figure 6,\(^{(9)}\) which shows that if \(q\) is greater than 0.91, there are no stable trajectories and no ions are transmitted.

Figure 6 Quadrupole stability diagram illustrating conditions for stable and unstable oscillations. (Reproduced with permission of J. Wiley & Sons, Inc., from J.R. Chapman, Practical Organic Mass Spectrometry, 2nd edition, J. Wiley & Sons, New York, 1983.)

Optimum resolution is obtained when \(a/q = 0.167\) and ions of a given \(m/z\) are transmitted when

\[
\frac{m}{z} = \frac{0.136V_0}{r_0^2 f^2}
\]

where \(V_0\) is in volts, \(r_0\) in centimeters, and \(f(= w/2\pi)\) is in megahertz. The instrument is usually operated at unit mass RP, i.e., throughout the scan, ions of mass \(m\) are resolved from those of mass \(m + 1\) so that the RP is equal to \(m\). The increase in RP with increase in \(m/z\) is due to the fact that the heavier ions move more slowly through the analyzer and so experience more oscillations than the lighter ions. Typically, \(r_0 = 0.4\) cm and \(f = 1\) MHz, so that for \(m/z = 10000\), and hence for an RP of 10000, \(V_0 = 11.76\) kV, which is usually considered to be impracticable. In practice, the effects of fringing fields become greater as the value of \(m/z\) rises, since the time spent in these fields is proportional to \(m^{1/2}\) and the transmission falls rapidly as \(m/z\) increases above about 1500. These effects are reduced by the use of a circular aperture at the entrance to the analyzer, so reducing radial divergence of the ions, and by the use of short RF-only pre- and postfilters to steer ions through the fringing fields. More generally, the RP is given by Equation (8):

\[
RP = \left(\frac{\text{length of quadrupole field}}{\text{radius}}\right)^2 \left(\frac{V_0}{E_i}\right)
\]

where \(E_i\) is the injection energy of the ions. If the upper practical limit of \(V_0\) has been reached, a reduction in \(E_i\) will increase the RP but at the cost of reducing transmission due to increased losses arising from radial translational energy.
Similarly, lengthening the quadrupole field is of limited value because of imperfections in the quadrupolar field leading to increased ion losses. Although the performance of commercial versions of these instruments has improved greatly during the 1980s and 1990s, the RP obtainable from a quadrupole mass analyzer rarely exceeds 2000. Higher RP can be obtained by reducing the operating frequency from the usual value of 1.2–1.5 MHz to a much lower value. Operating at 683 kHz, the upper mass range was extended to a little over 8500 at unit mass resolution and by working at fairly high pressure in the quadrupole collision cell collisional focusing resulted in there being only a small reduction in transmission.\(^{(10)}\)

### 2.3 Quadrupole Ion Trap

The first description of the ion trap was by Paul in 1956\(^{(11)}\) but a commercial version was not available until nearly thirty years later when it was marketed by Finnigan-MAT as the ion trap detector. Ion traps were initially developed as low-resolution low-mass detectors for use with gas chromatographs but since their introduction their performance has been improved considerably and several commercial versions are now available. As its name suggests, ions are stored within the trap and detection is accomplished by ejecting ions of a given mass-to-charge ratio to strike a conversion dynode before amplification of the signal by an electron multiplier. A mass spectrum is obtained by scanning an RF voltage as described below but ions which are not being ejected are stored rather than being lost as in the scanning of a magnetic sector or quadrupole instrument. A general introduction to the properties of ion traps has been given\(^{(12)}\) and an account of instrumental developments is contained in March\(^{(13)}\).

Although the ion trap is related to a quadrupole mass filter, the two instruments have very different properties and modes of operation. The ion trap can be considered to be generated by rotating the hyperbolic rod electrodes of a quadrupole analyzer about an axis perpendicular to the \(z\)-axis (the direction in which the ions travel) and passing through a point half way along the length of two opposing rods. The rods through which the axis passes form circular endcap electrodes and the other pair join up to form a doughnut-shaped ring electrode, as illustrated in Figure 7(a). The system is axially symmetrical and, ideally, the surfaces should be hyperbolic for maximum performance. Unlike the quadrupole analyzer, the ion trap is able to confine ions for long periods in a small volume close to the center of the trap. Ions may be generated within the trap or injected through an endcap electrode, after which they may undergo reactions prior to mass analysis.

There are several methods of operating an ion trap; the type and magnitude of the potentials applied to the electrodes vary with the type of experiment to be carried out. When used to produce a conventional analytical mass spectrum, a fixed RF voltage of frequency about 1 MHz with no DC voltage is applied to the ring electrode. All ions above a particular minimum \(m/z\), determined by the amplitude of the RF voltage, are stored and in principle there is no upper mass limit to the ions stored. If the amplitude of the RF voltage is increased, the low mass cut-off increases and ions are ejected in sequence through

\[V_{RF} = V_{RF} \cos(2\pi f_{RF} t)\]
an endcap electrode and detected externally. The upper mass limit is controlled by the maximum RF voltage that can be applied (typically 6 kV, peak-to-peak) and at the end of the voltage scan the RF voltage is removed and all remaining ions are lost to the walls or are swept out of the trap with the bath gas. The process is then repeated. This mode of operation is termed mass-selective axial instability ejection. Improved performance is obtained when a pressure of about $10^{-3}$ torr of helium is present in the ion trap, collisionally cooling the ions and forcing them into the center of the trap.

A further increase in RP is obtained by applying to the endcap electrodes a very low amplitude (e.g. 6 V, peak-to-peak) RF voltage of about half the frequency of the main RF voltage during the period when the latter is being ramped to produce an analytical scan. This results in ions of a particular $m/z$ being removed from the main cloud of ions immediately prior to their being ejected. Free from space charge effects, they are concentrated into a very tight bunch of ions just before ejection.

If a DC voltage is applied to the endcap electrodes together with the RF voltage applied to the ring electrode, the ion trap now has both a low-mass and a high-mass cutoff. By careful control of the voltages, a small mass range of ions or ions of a chosen $m/z$ can be isolated in the trap prior to its reactions being studied. Several alternative methods of controlling ion motion within the trap are based on using the main RF voltage on the ring electrode to confine the ions and an additional very low amplitude RF voltage, known as the “tickle voltage”, being applied to the endcap electrodes. If a single frequency or band of frequencies is applied and the duration and amplitude of the tickle voltage is controlled, resonant excitation of one or more ions over a chosen mass range may be effected, leading either to collision-induced decomposition of the ions or to their selective ejection. This may be used either to generate a mass spectrum or to remove unwanted ions prior to studying the reactions of those ions remaining in the trap.

The equations of motion for ions in the ion trap are similar to those that describe the motion of ions in a quadrupole mass analyzer. The parameters $a_z$ and $q_z$ are defined in a similar manner for motion in the $z$, or axial, direction and a plot of $a_z$ against $q_z$ again produces regions of stability and instability. Equations (9) and (10):

$$a_z = \frac{16eU}{m(r_0^2 + 2z_0^2)u^2}$$

$$q_z = \frac{8eV_0}{m(r_0^2 + 2z_0^2)u^2}$$

where the symbols are as defined previously. A typical ion trap and scanning sequence is illustrated in Figure 7.

The complex equations of motion are derived for a pure quadrupolar trapping field, but in practice better performance is achieved by the use of “stretched” geometry in which the separation of the end caps is about 11% greater than that calculated based on these equations. This modification of the geometry causes a significant shift in the resonant frequency for ions of a given $m/z$ but this is readily accounted for by the dependence of the frequency on the value of $r_0$.

Typical commercial ion trap instruments have RPs similar to or somewhat higher than those of quadrupole instruments. When operated in the mass-selective axial instability mode with axial modulation, the mass resolution obtainable for singly charged ions up to $m/z$ 650 is approximately $3 \times m$. Most instruments use an RF amplitude scanning rate of 5555 units of $m/z$ per second, which is equivalent to approximately 186 µs per unit of $m/z$. If the rate of scanning the RF voltage is considerably reduced, e.g. by a factor of $10^4$ or $10^5$, very high RPs can be attained. For example, when the rate of scanning of a standard commercial instrument was reduced from 5555 to 0.80 units of $m/z$ per second, a mass RP in excess of a million was obtained at $m/z$ 615, and even higher RPs have been obtained at still lower scanning speeds. More usefully, rather smaller reductions in the scanning rate can give very useful increases in RP. Accurate mass measurements at high resolution are still difficult because of variation of conditions in the ion trap causing multiple scans to give individual mass measurements of an ion spanning 0.2–0.3 Da. The accuracy can be improved considerably if (i) there is a phase-locked relationship between the main RF field and that of the axial modulation field and (ii) line-locking is used to minimize the noise level on the main RF field. When both of these were employed, the accuracy of mass measurement was better than 5 ppm at $m/z$ 264 and mass RPs in excess of 50 000 were achieved. It seems probable that RPs considerably above 2000 will be more common when one or more of the above techniques are employed more widely.

2.4 Time-of-flight Mass Analyzers

In principle, the time-of-flight mass analyzer is a very simple device. Ions at rest are subjected to a very short high voltage pulse of $V$ volts that sends the ions down a tube a distance $D$ to an electron multiplier with very high time resolution. Alternatively, since time-of-flight instruments are now used primarily with pulsed matrix-assisted laser desorption ionization (MALDI) sources, the accelerating voltage $V$ may be applied continuously as the pulses of ions are generated by the pulsed laser, the pulse width of which is typically less than a few nanoseconds. Reviews of developments in time-of-flight instrumentation have been published.
Whichever method is employed, all singly charged ions have, in principle, the same energy, $V_e$, so that from Equation (1), ions of mass $m$ have a velocity $v$ given by Equation (11):

$$ v = \left( \frac{2V_e}{m} \right)^{1/2} \quad (11) $$

Hence, for ions with masses $m_1$ and $m_2$ having velocities of $v_1$ and $v_2$,

$$ \frac{m_1}{m_2} = \left( \frac{v_2}{v_1} \right)^{1/2} \quad (12) $$

in other words $v$ is proportional to $1/m^{1/2}$. By recording ion current as a function of time, a mass spectrum is obtained because the times $t_1$ and $t_2$ taken by ions of masses $m_1$ and $m_2$ to reach the detector are given by Equation (13):

$$ \frac{t_1}{t_2} = \frac{v_2}{v_1} = \left( \frac{m_1}{m_2} \right)^{1/2} \quad (13) $$

From this equation, it is clear that $m = at^2$, so that $dm = 2at$ and the RP is given by Equation (14):

$$ \frac{m}{\Delta m} = \frac{t}{2 \Delta t} \quad (14) $$

The RP may therefore be increased by increasing $t$, e.g. by increasing $D$ or by reducing $V$. Although a high value of $V$ is usually required for reasonable sensitivity at higher mass, it leads to a marked increase in the energy spread of the ions caused by collisional processes that occur in the expanding plume of ions. It also increases the apparent spread in the times of formation of the ions. A reduction in $\Delta t$, the minimum time interval that can be measured at the detector, also improves RP. If ions of mass $m$ (Da) and charge $ze$ are subjected to an accelerating voltage of $V$ (volts), the velocity of the ions in meters per second is given by Equation (15):

$$ v = 1.39 \times 10^4 \left( \frac{zeV}{m} \right)^{1/2} \quad (15) $$

If $V = 20000$ V and $m = 5000$ Da, $v = 2.78 \times 10^4$ m s$^{-1}$ for a singly charged ion, so that for a flight path of 1.25 m, $t = 4.5 \times 10^{-5}$ s. If the minimum time interval that can be measured is 1 ns, the RP attainable is, in principle, 22 500, but in practice the performance is substantially below this for a variety of reasons.

Implicit in the above description is the assumption that all ions are formed at rest within a plane perpendicular to their direction of flight down the analyzer tube. These conditions are not fulfilled and ions leave the source with a spread of energies. If a large number of ions is formed, space charge effects cause the ion cloud to expand and increase the range of velocities of ions within the cloud, so that RP falls as laser power increases. As a result, the RP of a simple time-of-flight instrument is typically no more than 400 at $m/z$ 1500 and decreases rapidly at higher masses. The time resolution of the detector can be quite modest, e.g. 100 MHz, i.e. $\Delta t$ is 10 ns, in such instruments.

The earliest approach adopted to improve performance was the use of a “reflectron”, a repulsive electrostatic field, often known as an electrostatic or ion mirror, that reverses the direction of motion of the ions so that they are collected close to the source, as illustrated in Figure 8. A single uniform reflecting field gives only first-order time focusing of the energy spread of the ions. Improved performance is obtained by the use of a double reflecting field in which ions are retarded in the first field and reflected in the second field, enabling second order focusing to be achieved. The mirror may consist of one or two high transmission grids to produce a single- or two-stage reflector together with a series of annular concentric plates. In order to avoid edge effects and other grid-induced field distortions, the field is gridless, being defined simply by the annular plates through which the ions may pass. This essentially doubles the flight path, $D$, which is advantageous, but the main function of the reflector is to try to correct the effect of a spread of translational energy that arises during the ionization process by “bunching” of ions of the same $m/z$ ratio. Faster ions penetrate further than ions of average velocity into the electrostatic field so that they follow a slightly longer flight path in travelling from the source to the detector. Conversely, ions of below average velocity penetrate less far into the field and so travel a shorter path length. Typically, the use of a reflector increases the RP of an instrument which has a 1-m flight path from

---

about 400 to about 2000 at \( m/z \) 1500. Although this is a very useful increase in RP, neither the reflectron nor a high accelerating voltage can correct for ions formed at different times, e.g. in chemical reactions in the ablation plume.

Much greater improvements in RP can be obtained, however, if the method of ion extraction into the flight tube is improved. There have been two developments in source design that have tackled the problem of ion production in the source. Instead of the use of continuous extraction of ions from the MALDI source, a number of related techniques, known variously as time-lag focusing, pulsed delayed extraction, post source pulsed focusing, and so on have been described (see for example Vestal et al.\(^ {24} \)) and which resemble the technique first described by Wiley and McLaren in 1955.\(^ {25} \) Source designs based on these have been incorporated into commercial instruments since about 1997 onwards. In one version of time-lag focusing,\(^ {26} \) a voltage pulse of 2–3 kV that is a few nanoseconds wide is applied to extract ions formed on the source repeller plate from the source, and after a certain time lag or delay they encounter the full accelerating voltage of 20–25 kV as shown in Figure 9.

During the delay, newly formed ions of a given \( m/z \) are repelled from the repeller plate and from each other, so that they travel away from the plate into the field-free region with a broad distribution of velocities. With the repeller plate and first focus plate held at the same potential, the ions with the higher axial velocities travel further from the repeller plate than those ions with lower velocities, creating a distribution of ions within the field-free region. After a delay of about 0.5–5 \( \mu \)s, the short high-voltage extraction pulse is applied to the source repeller plate; more energy is imparted to ions close to the repeller plate than to those which are closer to the focus plate. The amplitude of the pulse or the delay time is adjusted so that ions close to the repeller catch up with the ions nearer the focus plate as they traverse the flight tube so that they reach the detector at the same time. These adjustments are \( m/z \) dependent and higher voltages and longer delay times are required to focus ions of higher \( m/z \).

Linear instruments of this type with a flight path of about 1 m are capable of resolving carbon isotope peaks at \( m/z \) 3000. Although the RP decreases with increase in \( m/z \), some commercial instruments with longer flight paths can attain an RP of about 5000 at \( m/z \) 2500. When combined with a reflectron, which gives further focusing of ions of a given \( m/z \), RPs in excess of 10000 are obtained up to \( m/z \) 10000. To obtain the best results from such instruments, a very fast response detector is required with a minimum measurable time difference of 1 ns or less and variations in the precise times of firing the laser and starting data collection (“jitter”) must be minimized. Although the focusing achieved is \( m/z \)-dependent, a broad mass range of ions can be observed at higher RP and the source can be adjusted to give optimum RP at the ions of the particular \( m/z \) of interest. An added advantage is that the accuracy of mass measurement is also improved and errors as low as 100 ppm up to \( m/z \) 30 000 Da are attainable. An example of a spectrum obtained by the use of this type of instrumentation is shown in Figure 10.

An alternative technique is to use orthogonal extraction of ions from the source.\(^ {27–30} \) This is particularly useful when the time-of-flight analyzer is the second mass analyzer in a tandem instrument for which time-lag focusing is less easy to use.\(^ {31} \) Even after collimation, the energy spread of the ion beam in the direction of the beam emanating from the collision cell is large but the energy spread in the plane perpendicular to the beam is very small. Ions pass into the source of a time-of-flight instrument and are extracted into the flight tube by means of a large voltage pulse applied perpendicular to the direction of the beam. When used in conjunction with a reflectron, instruments of this type can give mass RPs in excess of 10 000 at \( m/z \) 2500 and because of their high duty cycle they are intrinsically much more sensitive than a scanning instrument. Although this is well below the highest RP given by magnetic sector and FTICR instruments, the high sensitivity and very high \( m/z \) range of a time-of-flight
instrument makes this a very useful RP when working with samples that give ions above \( m/z 10000 \).

When a reflectron time-of-flight instrument is used to study products of ions that decompose in the flight tube after acceleration from the source (post-source decay), the resolution with which products may be observed is good only over a limited mass range. This is because the range of energies with which the ions are formed causes them to be focused at different points in the flight tube. A full spectrum of products is usually obtained by looking at several sections of the mass range in turn and then combining them to form a complete spectrum. In a tandem ToF/ToF instrument, the first reflectron improves precursor mass resolution and much higher resolution of product ions over a much wider mass range may be achieved by the use of a curved reflecting field.\(^{(32)}\)

### 2.5 Fourier Transform Ion Cyclotron Resonance Instruments

The technique of ion cyclotron resonance (ICR) mass spectrometry was introduced in the 1960s in the form of a low-resolution device and was used primarily to investigate the mechanisms of ion–molecule reactions of low mass species. FTICR mass spectrometry was first described by Comisarow and Marshall in 1974\(^{(33,34)}\) and since then it has been developed into a technique that is capable of very high-mass resolution, far outstripping that obtainable by any other type of mass analyzer.\(^{(35,36)}\)

Cells of various geometries have been described but the principles of operation of an ICR instrument will be illustrated by reference to the operation of the cubic cell as illustrated in Figure 11.\(^{(37)}\)

Detection of ions of mass-to-charge ratio \( m/z \) is based on the absorption of RF power at the ICR frequency, \( \omega_c \) (radians s\(^{-1}\)), which is approximately given by Equation (16):

\[
\omega_c = \frac{zeB}{m}
\]

where \( z \) is the number of electronic charges \( e \), and \( e \) is expressed in coulombs, \( B \) is the magnetic induction in tesla and \( m \) is the mass of the ion in kilograms. Since \( \omega_c \) can be measured with an accuracy of about

1 part in $10^8$, this in principle provides the basis for very high-mass resolution and accuracy of mass measurement. Furthermore, ions are not destroyed on detection, so that their concentrations can be monitored as a function of time, allowing a variety of multiple resonance experiments to be performed. Typical values of $B$ for commercial instruments range from 3.0 to 9.4 T and mass RPs of well over a million have been obtained for low mass ions and of several hundred thousand for multiply charged biomolecules with $m/z$ in the region of 1000–2000.

In the basic cubic cell shown in Figure 11, ions are generated by electron ionization by passage of an electron beam through the cell along the $z$-axis. In most applications, ions are generated either by MALDI or ESI in an external source and are introduced into the ICR cell for reaction or analysis. Once inside the cell, the motion of the ions is extremely complicated and three different types of oscillation can be distinguished. In the presence of the strong magnetic field, ions execute cyclotron motion about the $z$-axis in the $xy$ plane but they are free to move along the $z$-axis. A small trapping voltage, usually in the region of 1 V, of the same sign as the charge on the ions to be trapped, is therefore applied to the two plates that are in the $xy$ plane perpendicular to the magnetic field. This effectively prevents loss of ions along the $z$-axis but also modifies the motion of the ions so that three types of oscillation have to be considered:

1. cyclotron motion about the $z$-axis
2. magnetron motion due to the precessing of the cyclotron motion about the $z$-axis
3. $z$ oscillation in which ions oscillate between the trapping plates.

The angular frequencies of these three types of motion in a cubic cell are given by Equations (17–19):

\[
\text{Cyclotron} \quad \omega_c = \frac{[zB + (z^2B^2 - 4mzE_0)^{1/2}]}{2m} \quad \text{(17)}
\]

\[
\text{Magnetron} \quad \omega_m = \frac{[zB - (z^2B^2 - 4mzE_0)^{1/2}]}{2m} \quad \text{(18)}
\]

\[
\text{$z$-Trapping} \quad \omega_T = \left( \frac{2}{d} \right) \left( \frac{zV_T}{m} \right)^{1/2} \quad \text{(19)}
\]

where $E_0 = 2aV_T/\alpha^2$, $\alpha$ is a geometrical factor equal to 1.386 for a cubic cell and $a$ is the length of the cell. $V_T$ is the trapping voltage applied to plates of separation $d$. Equation (17) therefore gives a better estimate than the simple Equation (16) for the relationship between $\omega_c$ and $m$, but space charge effects which vary with the number of ions in the cell cause a slight reduction in $\omega_c$ for a given ion, so that Equation (17) is only approximate. In addition, the effects of space charge and trapping voltages are slightly different for cells with different geometries.

Ions are excited by the application of an electrical signal of frequency $\omega_c$ across the upper and lower plates of the cubic cell. The radius to which the ions are excited is independent of their mass but is a function of the amplitude and duration of irradiation. Radiation of constant amplitude over the frequency range required to excite all ions of interest is required for constant sensitivity over the whole mass range. The excitation of the ions causes an RF current across the plates which is proportional to the number of ions of the particular mass-to-charge ratio that are being excited. In FTICR, a “chirp” or short burst of RF radiation of constant amplitude during which the frequency is scanned rapidly was originally used to excite the ions. This has the disadvantage of exciting the motion of the ions along the $z$-axis, the extent of which is mass dependent. As a result, alternative methods of excitation have been employed, of which stored waveform inverse Fourier transform (SWIFT) excitation is increasingly used.\(^{38}\) This has the advantage of being able to eject ions in a mass selective manner so that unwanted ions can be removed from the cell, thereby reducing space charge effects.

The maximum theoretical mass RP obtainable in an ICR cell is given by Equation (20):

\[
R = \text{constant} \times \frac{zeB}{mP} \quad \text{(20)}
\]

where $P$ is the pressure within the cell. The RP therefore is predicted to fall linearly as $m/z$ and $P$ rise but to rise linearly with increase in magnetic field strength. The highest RP is therefore obtained with instruments having high field magnets (7.0 or 9.4 T) and an operating pressure in the region of $10^{-3}$ torr. In practice, for multiply charged ions of biological samples with $m/z > 2000$, the RP falls off more rapidly than is predicted by Equation (18) owing to the increased effects of nonideal electric fields. More complex cell designs attempt to overcome this problem but the design usually requires a compromise to be made between RP and efficiency of ion trapping. Because the effects of ion trapping voltages and space charge vary with cell design, the precise relationship between $\omega_c$ and $m/z$ is difficult to establish. Consequently, although very high RP can be obtained, the accuracy of mass measurement based simply on the measurement of $\omega_c$ without calibration is difficult to predict.

One of the problems is that on excitation, the ions move away from the cell axis and have a wide spatial distribution caused by the increased radius of the cyclotron and magnetron motions of the ions, leading to reduced mass RP. Various ion cooling techniques have been used to concentrate the ions into a tight spatially confined packet.
prior to injecting them into the ICR cell along the z-axis. A buffer gas rapidly reduces the amplitudes of cyclotron and z-trapping oscillations but increases the amplitude of magnetron motion with deleterious effects. This motion increases as the pressure, ion density and trapping field increase and in extreme cases can lead to the loss of ions. Even under less extreme conditions, the coherence of the ion cloud is reduced, resulting in decreased RP and sensitivity, especially for ions with a higher mass-to-charge ratio.

A promising development, first used in Penning traps, is quadrupolar excitation which makes use of irradiation by means of an RF electric field of two-dimensional azimuthal quadrupolar symmetry. This has the property of converting the troublesome magnetron motion into cyclotron motion. Since cyclotron motion is rapidly removed by collisions of ions with a buffer gas, the use of quadrupolar excitation and a buffer gas effectively cool all three types of ion motion so that the ions are confined to the cell axis. The technique is therefore often referred to as quadrupolar axialization. It produces both a dramatic increase in RP and sensitivity and also an increase in efficiency of ion trapping, so that it is possible to measure the ion current repeatedly with an efficiency of remeasurement approaching unity. This not only allows the detection of samples at attomole levels but also allows sensitive time-dependent experiments to be carried out at high resolution.

The dynamic range of the basic cubic cell ICR instrument is about $10^5$ because with fewer than $10^5$ ions in the cell, ion statistics problems begin to appear and with more than $10^5$ ions in the cell, space charge effects become an increasing problem. For high RP operation, fewer than $10^5$ ions are usually required. The techniques of SWIFT and quadrupolar axialization largely overcome this problem because SWIFT can be used selectively to eject unwanted ions, reducing space charge effects, and quadrupolar axialization allows remeasurement of relatively few ions under well-controlled conditions.

As a result of these improvements in controlling the ion motion within the ICR cell, the FTICR instrument now offers the highest RP at the highest sensitivity of any commercially available mass spectrometer. As larger magnetic field strengths become available, performance will continue to increase because many of the desirable features of this type of instrument improve either linearly or quadratically with the strength of the magnetic field. The increased size of the magnets will require that ions made in external sources can be transferred with high efficiency over the increased distance between the source and ICR cell by means of an octopole ion guide.

3 APPLICATIONS

3.1 Applications Involving Determination of Elemental Composition

If the RP is sufficiently high to separate all components having the same nominal mass, i.e. the “chemical noise” is removed, an accurate mass measurement is frequently sufficient to provide an elemental composition of an ion which, in many circumstances, is sufficient to identify the component unequivocally. One of the major driving forces for the development of high-resolution electron ionization mass spectrometry at the beginning of the 1960s was the need in the oil and petroleum industries to identify sulfur-containing compounds present in complex mixtures of hydrocarbons. A major difficulty was differentiating between hydrocarbons and sulfur-containing compounds of the same nominal mass in which three $^{12}$C atoms had been replaced by one $^{32}$S and four $^1$H atoms, increasing the mass by only 0.003371 Da. Even with an RP of 100 000 which was attainable when using a large double-focusing magnetic sector instrument, it is possible to resolve ions of this type only up to about 340 Da, and only then if it is assumed that no other ions interfere.

The wider applicability of this technique was quickly recognized by synthetic chemists and one of the most common uses of high-resolution mass spectrometry is in verifying that the mass of a newly synthesized compound is in agreement with that calculated from isotopic masses. In the absence of any appreciable background spectrum, an accuracy of ±5 ppm is usually deemed to be sufficient to verify the elemental composition of a compound. Similarly, the accurate mass measurement of a fragment ion can indicate its elemental composition and hence that of the neutral species lost, but in this case high RP is required because different fragmentation reactions may lead to ions of different elemental composition that have the same nominal mass. A straightforward example of the need for this is in demonstrating that certain peaks in the mass spectra of ketones are doublets arising from both alkyl and acyl ions. The $m/z$ 57 ion in the mass spectrum of 3-heptanone, $n$-$C_7H_{14}COC_2H_5$, is a mixture of the ions $C_4H_9^+$ and $C_7H_8CO^+$, the accurate masses of which are 57.0704 and 57.0364 Da, respectively. Since the mass difference is 0.0340 Da, the peaks are fully resolved at a relatively low RP of about 1600 but similar pairs of ions at higher masses require increasingly high RP to separate them.

A somewhat more complicated use of high RP is in the identification of a component in a complex mixture. Here, there may be many more components that can potentially interfere with the observation of the peak of interest and the RP employed must be sufficiently high to cope with this. A simple example of this type of application is the detection of traces of the potent
carcinogen dimethylnitrosamine, (CH$_3$)$_2$NNO, for which the accurate molecular weight is 74.0479 Da. In foodstuffs, this may often occur together with methyl acetate, which has an accurate molecular weight of 74.0367 Da, a difference in mass of 0.0112 Da. An RP of approximately 6600 is required to separate these peaks, allowing high-resolution single ion monitoring to be used to detect dimethylnitrosamine directly from the effluent of a gas chromatograph.

A further example of the use of high RP to assist in compound identification is the detection of 2,3,7,8-tetrachlorodibenzodioxin, the most abundant ion of which, in the molecular ion region, has a nominal mass of 322 Da. This is due to the ion $^{12}$C$_{12}$H$_4$S$^{35}$Cl$_3$$^{37}$Cl, for which the accurate mass is 321.8936 Da. A number of other ions of chlorinated species have closely similar masses, the closest being those of composition $^{12}$C$_{12}$H$_6$O$^{35}$Cl$_2$$^{37}$Cl and of mass 321.9114 Da, a mass difference of 0.0178 Da. In order to resolve the peaks from these two ions, an RP in excess of 18000 is required together with high stability of the mass calibration of the instrument.\(^{(42)}\)

### 3.2 High-resolution Electrospray Ionization Mass Spectrometry

The use of high RP to enable the elemental composition of an ion to be determined as described above becomes increasingly reliable as $m/z$ rises, and above $m/z$ 700–800 the number of different possible isotopic compositions rises rapidly. Frequently, many of these can be excluded on other grounds, so that the method is still of value in showing that the measured mass is consistent with the proposed elemental composition, though it is rarely possible to determine this unequivocally. The two major ionization methods introduced in the mid-1980s, MALDI and ESI, were initially interfaced to low-resolution time-of-flight and quadrupole mass analyzers and were used to obtain approximate molecular weights of sample of 10 000–50 000 Da to ±0.1%. It was not until they were used in conjunction with an FTICR mass analyzer and later with an ion trap that interest in new applications of high-resolution mass spectrometry revived in about 1990.

Peaks observed in a low-RP ESI spectrum are generally unresolved clusters of isotope peaks. In the absence of any interfering peaks, these can be used to give an estimate of the average or “chemical” molecular weight of a sample provided that the number of charges carried by the ion can be determined. If an ion carries $z$ charges, the separation of peaks on the $m/z$ scale is 1/$z$ units. Hence, for an ion of nominal mass 10 000 Da carrying 10 charges, $m/z = 1000$ and the separation between peaks on the $m/z$ scale is 0.1 unit. The RP needed to separate these peaks is 1000/0.1 or 10 000, which is readily attainable in an ESI/FTICR instrument. This method of using high RP to separate isotopic peaks, to determine the number of charges from the separation of the peaks and so to measure masses to an accuracy of less than 1 ppm has now been accomplished in a number of laboratories. This is particularly valuable in determining the products of collision-induced decomposition induced by sustained off-resonance irradiation (SORI). In the case of the +10 charge state of ubiquitin at $m/z$ 857, McLafferty et al. have obtained an RP in excess of 2 000 000\(^{(43)}\) and fragments of masses in the range 1000–7000 Da have been measured to an accuracy of better than 0.1 ppm.\(^{(44)}\)

The isotopic resolution of ions of mass above 30 000 Da initially proved difficult but this was first accomplished by McLafferty’s group when they resolved the +43 charge state of electrosprayed albumin with an RP of 166 000.\(^{(45)}\)

It is important to note, however, that above about 30 000 Da, the measured mass is not the mass of a monoisotopic ion. Each such “peak” consists of a large number of superimposed peaks due to ions of the same nominal mass containing different numbers of $^{13}$C, $^{15}$N, $^{34}$S, and so on, heavy isotopes. In general, the RP required to separate these peaks is appreciably higher than that available and the measured mass is therefore an average value rather than that of a single ion. The monoisotopic peak due to ions consisting entirely of light isotopes is not observed because the probability of forming such a molecule is vanishingly small. The position of this peak can be estimated by matching the experimentally observed isotopic abundances to those calculated for a protein of average amino acid composition, but slight errors in the measured abundances may lead to errors of more than 1 Da.\(^{(46)}\) An alternative approach is to express a protein from a medium that contains $^{13}$C-depleted glucose and $^{15}$N-depleted ammonium sulfate, thereby considerably increasing the probability of forming the monoisotopic molecule and so observing directly the peak due to this ion. This significantly increases the upper mass limit at which the accuracy of mass measurement is within 1 Da and facilitates the identification of variants and various types of adduct.\(^{(47)}\)

The gas phase conformations of proteins can be probed by observing the rate and extent of H/D interchange between D$_2$O and multiply charged protein ions contained in the cell of an FTICR instrument. An early example is shown in Figure 12 of electrosprayed equine cytochrome-c in the presence of D$_2$O in which the isotopic envelope of the 11+ ion is shown as a function of time.\(^{(48,49)}\) In general, several different rates of exchange were observed, reflecting the ease with which certain groups of protons could be exchanged. These, in turn, reflected the gas phase conformations of the proteins, exchange being more rapid and extensive for more open conformations of the protein, so that changes in conformation can be followed by changes in the extent
of H/D interchange. If the gas phase data are assumed to reflect accurately the relative concentrations of species in solution, the rate and extent of H/D interchange in solution can also be followed by high-resolution mass spectrometry. Subsequently, by using enzymatic digests and tandem mass spectrometry, the position of the H/D exchange within the protein may be determined. The RP required to follow H/D exchange in a protein is not less than unit mass resolution in the region of the molecular ion of the protein, i.e. typically 30 000–50 000.

4 CONCLUDING REMARKS

After a period during which the importance of high RP and accuracy of mass measurement appeared to decrease, the application of mass spectrometry to high molecular weight biological molecules has brought a resurgence of interest in these topics. Instrumental improvements in time-of-flight and ICR instruments now offer good high-resolution performance at relatively high masses. These will be increasingly important in studies of detailed mechanisms of reactions of peptides and proteins and high-resolution mass spectrometry will doubtless play an important role in such studies.

Mass spectrometry is an analytical technique used to measure the composition of a substance by isolating specific analyte components according to their individual atomic or molecular mass-to-charge ratios. Inorganic mass spectrometry is specifically used to determine the elemental and isotopic composition of the material being analyzed.

The techniques are capable of the measurement of a range of concentrations from major components to ultratrace constituents.

Several instrumental approaches are used to separate and measure the abundance of component ions formed from the sample. These techniques include electron ionization mass spectrometry (EIMS), inductively coupled plasma mass spectrometry (ICPMS), thermal ionization mass spectrometry (TIMS) and spark source mass spectrometry (SSMS). These techniques utilize a variety of mass spectrometers including ion trap, quadrupole, magnetic sector and time-of-flight mass analyzers, depending on the type of sample being analyzed and the desired quality of the results. Often sample introduction techniques can be utilized to enhance the capabilities for solving specific analytical chemistry problems.

1 INTRODUCTION

Mass spectrometry is an analytical technique used to measure the composition of a substance by isolating specific analyte components according to their individual atomic or molecular mass-to-charge ratio (m/z). In order for these components to be separated from each other for measurement, they are converted from their native form (indigenous form in the original sample) into a stream of ions, prior to an isolation process using a mass spectrometric technique. The mass spectrometer is a device that is used to separate each of the ions, measure their relative m/z (to identify the nature of the component qualitatively), and finally measure their ion current, which is proportional to the analyte concentration.

Several approaches are used to convert gas, liquid and solid samples to ions for subsequent mass spectrometric measurement. These techniques, which are identified as EIMS, TIMS, SSMS, ICPMS and glow discharge mass spectrometry (GDMS), are used for the solution of specific analytical chemistry problems. In addition, various types of sample introduction techniques, including pneumatic nebulization, electrothermal vaporization, laser ablation and spark ablation, are used in specific analytical chemistry applications.

Instrumental methods used to separate the ions according to their m/z, or effectively to serve as a mass filter, employ approaches based upon a variety of techniques. These techniques use principles such as (1) the angular dispersion of individual m/z ions in an ion beam as it transverses through a magnetic field; (2) the differences in time required for ions of different m/z to drift a fixed distance after reaching constant acceleration; (3) the use of a tuned radiofrequency (RF) electrostatic
field to reject all \( m/z \) ions that have spiral paths other than the one that resonates, thereby functioning as a mass filter; and finally (4) the use of electrostatic lenses to trap ions within an RF field, followed by the controlled release of specific \( m/z \) ions by variation of the lens’ potential. Combinations of ionization procedures and spectrometric techniques result in analytical instruments suitable for the measurement of major, minor and trace concentrations of elements in a variety of materials. In addition, many of these combinations are used for the measurement of stable isotopic abundances, which are required for stable isotope dilution quantitation, isotopic tracer studies and isotope geochronology.

2 MASS SPECTROMETRIC ANALYSIS OF INORGANIC MATERIALS – HISTORICAL PERSPECTIVES

The technique of mass spectrometry was first introduced by J.J. Thomson in 1913. Thomson employed the principle to identify the isotopes of neon. He used a combination of electric and magnetic fields to separate ions of \( ^{20}\text{Ne} \) and \( ^{22}\text{Ne} \) originating from an electrical gas discharge. The first identifiable mass spectrograph was designed in the early 1920s by F.W. Aston. In these early years mass spectrometry was primarily used for the measurement of elemental stable isotopes, for which Aston was awarded the Nobel prize. Shortly after winning the prize, Aston incorrectly predicted that the future usefulness of the technique would be limited. However, in the early 1940s, mass spectrometry found use in the field of organic analytical chemistry for molecular structure identification and hydrocarbon analysis.

In the 1950s, the first mass spectrometer, which was designed specifically for inorganic analytical chemistry, utilized an RF spark discharge as an ionization source. The primary advantage of this technique, in addition to the ability to measure stable isotopes of analyte elements, was the capability to determine elements at sub-parts per million concentration levels for both easy and difficult to ionize atoms, and its ability to perform analysis of solid samples directly, without the need for sample dissolution.

The first use of a plasma as an ion source for inorganic mass spectrometric analysis was reported by A.L. Gray in 1975. He used a DC (direct current) capillary arc for analyte ionization. This was rapidly followed by the use of an inductively coupled plasma (ICP) for sample atomization and ionization, patterned after the popular atomic emission spectrometric approach that was being extensively used in many laboratories for trace element analysis.

3 TECHNIQUES USED FOR INORGANIC MASS SPECTROMETRY

3.1 Electron Ionization Mass Spectrometry
EIMS is used in inorganic analysis for the determination of noble and permanent gases such as \( \text{H}_2, \text{O}_2, \) and \( \text{N}_2 \). In addition, other components such as carbon and sulfur can be determined after oxidation, by the measurement of the ionized oxide molecules, \( \text{CO}_2 \) and \( \text{SO}_2 \). The instrument uses a gas inlet system coupled to a conventional magnetic sector mass spectrometer, sometimes equipped with multiple detectors to provide simultaneous multi-constituent or multiisotope determinations. The sample in a gaseous form is introduced through a controlled leak gas inlet system (see Figure 1) into the ionization source, where collision of analyte species occurs with a beam of accelerated electrons. This collision of electrons, which typically are accelerated to an energy of approximately 70 eV, with components of the sample causes ionization of the sample atoms or molecules. These ionized atoms or molecules are then separated according to their \( m/z \) by the mass analyzer and measured by the detection system of the spectrometers.

In addition to permanent gases, selected metals can also be determined as gaseous species. Mercury, because it has a high vapor pressure at room temperature, can be measured directly in its elemental state. Other metals such as selenium can be determined when bonded to volatile organic compounds. For example, the isotopic composition of calcium has been determined using volatile chelate compounds formed with trifluoracetylaceetone. Other metals such as chromium and nickel (using dithiocarbamate) can be determined in a similar manner.

This technique provides an ideal approach for the high precision determination of isotope ratios of constituents. In addition, the ability to measure isotopic composition

![Figure 1 Gas inlet system for EIMS.](image-url)
allows high accuracy isotope dilution quantitation to be performed.

### 3.2 Spark Source Mass Spectrometry

SSMS is a technique that was designed for the direct trace elemental analysis of solid samples requiring a minimum of sample preparation. In 1934, A.J. Dempster introduced a spark source, created by an RF (1-MHz) oscillating potential of several kilovolts, applied to electrodes formed from the sample material. If the sample is electrically nonconducting, it is mixed with a conducting binder. This spark initially vaporizes and atomizes the components of the sample, followed by the immediate ionization of the atomized elements.

In 1954, N.B. Hannay described the first practical analytical instrument utilizing the spark source. Modern analytical instrumentation uses the spark source to create ions of the components of the sample, which by electrostatic acceleration form an ion beam whose composition is representative of the original sample. This composite ion beam is separated into individual analyte ion beams by a double-focusing mass spectrograph utilizing the high resolution Mattauch–Herzog geometry. The resolved ion beams are focused on a nearly flat focal plane, where an ion sensitive emulsion on a photographic plate is used as a detection system. The photographic plate offers the combination of an integrating detector, which provides high sensitivity with truly simultaneous multielement detection. A fixed position electron multiplier can also provide “electrical detection”, which by controlled variation of the magnetic field provides mass scanning capability.

This technique provides the capability for the direct determination of about 70 elements in solid material, without the need for extensive sample preparation, with a sensitivity of within a factor of 2–3 for all elements. Detection limits in the 1–100 ppb range can be achieved with a few milligrams of sample. Calibration curves demonstrate linearity of over five orders of magnitude, ranging from major components down to trace constituents on a single analysis. Although the technique offers many unique analytical capabilities, it does not provide high measurement reproducibility. The combination of the limited stability of the spark discharge and its ability to atomize the sample, the inhomogeneity of the distribution of the analyte elements in the sample and the variations in the ion beam due to changes in the electrode gap during sample vaporization limit the precision of ion current measurements to ±10–20% relative standard deviation (RSD) depending on the integration time. This relatively poor reproducibility limits the absolute accuracy that can be achieved in routine operation. The use of isotope dilution quantitation for selected elements overcomes this limitation. Because of this problem with reproducibility, multielement SSMS is often used as a semiquantitative trace element survey technique.

### 3.3 Thermal Ionization Mass Spectrometry

Sample in the form of a liquid solution of chloride or nitrate salts is deposited on the surface of a refractory metal filament, usually made of tantalum, rhenium, tungsten or thoriated tungsten (to lower its work function). The filament is resistively heated to over 1000°C by passing an electrical current through it. The heating process sequentially vaporizes the analyte followed by immediate thermal ionization at the surface of the metal filament due to the low work function of the filament metal (Figure 2). Table 1 shows the respective melting temperatures and work functions of the typical filament metals. Thermal sources can consist of a single, double or triple filament. Single filament ion sources are used both to vaporize and ionize the analyte element at the same filament surface. With the double and triple filament ion sources, sample vaporization occurs from the first filament followed by adsorption of the gaseous

sample on the second or third filament, where ionization takes place by transfer of an electron from the analyte to the filament metal.

Elements that have a first ionization potential of $<7\text{ eV}$ are directly ionized by this technique with high efficiency. This includes elements such as alkalis, alkaline earths, actinides and rare earths. Other elements, such as 1st and 2nd row transition elements that have first ionization potentials greater than 7 eV, often require matrix modifications to enhance their ionization efficiency. For example, silica gel is added for the analysis of elements such as cadmium, copper, lead, silver and zinc. In addition, negative ions can also be formed for elements such as the halogens, selenium, sulfur and tellurium, by transfer of an electron from the filament metal to the analyte atom.

Ions produced by this thermal ionization process are separated and quantitatively measured by a mass spectrometer, hence the name TIMS. Since predominately singly charged ions are formed, the mass spectrum is relatively simple. Instruments utilizing quadrupole mass spectrometers or medium resolution single-focusing magnetic sector mass spectrometers are used for separation of the ions formed by this method. This approach can produce very high precision isotope ratio measurements, which can be effectively utilized for isotopic measurement applications such as geochronology or quantitation of the ions formed by this method. This approach can produce very high precision isotope ratio measurements, which can be effectively utilized for isotopic measurement applications such as geochronology or quantitation employing the isotope dilution procedure.

### 3.4 Inductively Coupled Plasma Mass Spectrometry

The ICP is a high electron collisional temperature (10 000 K) inert gas (usually argon) medium, sustained by a high-power (1–2 kW) RF electromagnetic field. The plasma is confined in a quartz torch, sustained by the electromagnetic field, which is coupled to the plasma gas via an external antenna (load coil), thereby eliminating artifacts originating from internal electrode materials (Table 2).

The ICP has been extensively used as an atomic emission source for trace element analytical chemistry. It has the unique features of being able to atomize efficiently essentially all elements in the periodic table, including the refractory (high-boiling-point) elements. The ability to form predominantly singly charged ions of all the elements, with low probability of the formation of doubly charged ions (owing to the 15.76-eV ionization energy of argon, which is less than the 2nd ionization potential of most elements), results in a simple mass spectrum. The chemical inertness of the noble gas medium reduces the prevalence of interference effects.

The sample, in liquid form, is introduced into the plasma as a gas-transported aerosol, produced by pneumatic nebulization. When entering the plasma the aerosol is initially desolvated, followed almost immediately by thermal atomization. As the atoms are transported into the higher energy regions of the plasma, ionization takes place, primarily by a collision mechanism with accelerated argon ions and electrons from the plasma. The analyte ions are mechanically extracted from the plasma through the orifice of a sampling cone made of nickel or platinum. Ions extracted from the plasma form an ion beam, which is further refined by the orifice of an internal skimmer cone. This ion beam, which has a composition representative of the original sample, passes into the mass analyzer where individual ion beams of each of the components are isolated and sequentially transported to the electron multiplier detector.

Other sample introduction techniques such as laser ablation, electrothermal vaporization, or direct insertion devices provide a method for nonliquid samples to be quantitatively introduced into the plasma. Each of these techniques offers special characteristics, which can be utilized for the solution of specific analytical chemical problems.

Most ICPMS instruments employ a quadrupole mass analyzer for isolation of individual ion currents. This equipment provides basic unit mass resolution capability, which is usually sufficient for most analytical applications (Figure 4). For the solution of specialized analysis problems, the coupling of the ICP with a high-resolution magnetic sector mass spectrometer provides the capability for analyte ions to be separated from isobaric interferences in the mass spectrum, thereby allowing high accuracy determinations.

### 3.5 Glow Discharge Mass Spectrometry

Because of their simplicity and stability, low-pressure DC and RF discharges were used as ionization sources in early mass spectrometers. The modern technique of GDMS consists of a sample enclosed in a glow discharge cell (see Figure 3). An inert gas, usually argon or neon, at low pressure (0.1–100 mbar) is used to form a glow discharge (low-pressure plasma). For DC glow discharges, the sample must be an electrically conducting material or a nonconductor mixed with a conductor, such as graphite.

as a binder. RF glow discharges can analyze nonconductor samples directly.

The sample is usually configured as the cathode in the glow discharge cell, with the anode forming the housing of the cell. The surface of the sample is sputtered by the high-energy argon ions of the inert gas ions of the discharge, which vaporizes and atomizes the analyte species into the cell. After atomization, the analyte atoms are ionized by a collisional mechanism similar to that employed in atmospheric pressure plasmas. Ions are removed from the glow discharge cell through an extraction orifice. An ion beam is formed from the ions extracted from the cell. This beam is accelerated and focused by ion lenses and directed into the mass spectrometer. Both magnetic sector and quadrupole mass analyzers are commonly used with glow discharge sources.

GDMS has been extensively utilized for the determination of trace elements in pure metals and alloys (i.e. steel, high-duty nickel alloys, gold, aluminum, etc.) and in various semiconductor materials (i.e. silicon, gallium arsenide, etc.) High sensitivities produce detection limits for most elements in the parts per trillion range.

4 DESCRIPTION OF MASS SPECTROMETERS

The designs of mass spectrometers used in inorganic chemistry applications are basically the same as those used in organic mass spectrometry. Variations of three basic types of mass spectrometer are employed depending upon the specific application: the combination of magnetic and electrostatic fields for separation of ions (magnetic/electrostatic sector), the time separation of ions (time-of-flight), and the use of resonance mass filters (quadrupole/ion traps).

4.1 Magnetic Sector Mass Spectrometers

The classical type of mass spectrometer, the magnetic sector instrument, as the name suggests, employs a magnetic field to separate various m/z ions from each other, so that they can be measured independently. It is based on the principle that a charged particle, traveling at a constant velocity, perpendicular to the lines of force of a magnetic field will be deflected at an angle proportional to the mass and charge on the particle. Equation (1) describes the mathematical relationship between the accelerating voltage \( V \), mass \( m \) and charge \( z \) of an ion and its radius of curvature \( r \) as it passes through a fixed magnetic field \( H \)

\[
r = \frac{(2Vmz)^{1/2}}{H}
\]

From this equation, it is apparent that the radius of curvature of a specific \( m/z \) ion is proportional to the square root of the mass of the ion. Therefore, an ion beam of a mixture of \( m/z \) ions will be separated into multiple ion beams that can be resolved for independent measurement.

A single-focusing magnetic sector instrument is the simplest mass spectrometer. It utilizes an ion beam accelerated to a constant velocity passing through a magnetic field. For multielement determinations, the resolved analyte ion beams are simultaneously detected by a photographic emulsion, or for single ion monitoring, the specific ion beam is isolated by an exit slit and measured with an electron multiplier detector.

A double-focusing mass spectrometer combines the previously described magnetic sector with an electrostatic analyzer. The electrostatic analyzer serves as an energy-focusing device to improve the energy distribution of the ion beam. Ions of a common \( m/z \) but with different energies can be focused with an electrostatic analyzer. This arrangement provides higher resolution (i.e. the ability to separate ions of similar mass). Double-focusing mass spectrometers can be configured with the
electrostatic analyzer either in front of or behind the magnetic sector.

When the electrostatic analyzer is positioned behind the magnetic sector, the instrument is named the “reverse Nier–Johnson geometry”. This arrangement provides for focusing for only one \( m/z \) ion at a time. Therefore, it is only suitable for the use of a single \( m/z \) ratio detection system. Multiple ions are detected individually by scanning the magnetic field to position different \( m/z \) ions on the detector sequentially in time.

The “Mattauch–Herzog geometry” spectrometer has the magnetic analyzer positioned behind the electrostatic analyzer (see Figure 4). This type of arrangement permits double focusing for all masses simultaneously, providing the ideal geometry for multielement detection using a photographic emulsion.

The primary characteristic of magnetic sector instruments is their ability to operate at high resolution. Double-focusing mass spectrometers can easily operate at a resolution of 10,000. This means that the instrument has the ability to separate an ion with an \( m/z \) of 250 from one with an \( m/z \) of 250.025. This capability allows the isobaric interference of a molecular ion to be resolved from the analyte ion. For example, the resolution that is required for the separation of the \( ^{40}\text{Ar}^{16}\text{O}^+ \) and \( ^{40}\text{Ca}^{16}\text{O}^+ \) ions from the \( ^{56}\text{Fe}^+ \) analyte ion, at the nominal mass of 56, is approximately 4000. Most mass spectrometers that cannot operate at this resolution will not be able to analyze iron accurately at \( m/z \) 56 in an argon plasma with calcium present.

### 4.2 Quadrupole Mass Spectrometers

The quadrupole mass analyzer is a device that essentially rejects all \( m/z \) ions except the unique one that is permitted to pass through the tuned RF and DC electrical fields, thereby serving as a mass filter. The quadrupole device consists of four precisely machined cylindrical rods arranged symmetrically parallel to each other (see Figure 5). The central space between the four rods is aligned concentric to the ion beam, which is accelerated and focused by electrostatic ion lenses. The ion beam is a composite of a mixture of ions representative of all of the components of the sample. As this mixture of ions with different \( m/z \) pass through this center space and travel parallel to the length of the quadrupole rods, only a single \( m/z \) ion species is permitted to traverse this space unimpeded and exit the opposite end where it is focused on an analog cup or electron multiplier detector (Figure 6).

The ion isolation process involves the application of both DC and RF potentials to opposite rods in the quadrupole rod set. The electromagnetic field created by these potentials on the rods interacts with the beam of mixed ion species. In this applied field, each \( m/z \) ion is deflected in a spiral path as it traverses through the space between the rods. All ions, except the one with an \( m/z \) tuned to the applied fields, will be deflected into the quadrupole rods. The single unique \( m/z \) ion which is tuned to the applied field is allowed to pass through the rods and on to the detector.

Ions with different \( m/z \) values can be scanned by continuously varying the field between the quadrupole rods. This field can be changed in a uniform fashion by altering either the applied DC potential or the frequency of the RF voltage. Thus by continuously varying the applied potentials on the quadrupole rods as a function of time, the \( m/z \) values of the ions passing through the spectrometer are changed in a uniform fashion. This results in a scan of the mass spectrum of the ion beam. A spectrum obtained from a quadrupole mass analyzer is shown in Figure 7. Scanning provides a suitable method for rapid multielement qualitative analysis. Peaks representing specific \( m/z \) ions are characteristic of components in the sample. Measuring the intensity of these peaks can be used to estimate the concentration of the specific component by comparison with a known concentration standard.

Another mode of operation, sometimes called “peak hopping” can be used to perform quantitative analysis of a specific group of one or more elements. This technique involves predetermining the necessary applied potentials to the quadrupole rods to permit the appropriate \( m/z \) ion to pass. These calibrated potentials can be

---

INORGANIC SUBSTANCES, MASS SPECTROMETRIC IN THE ANALYSIS OF

Figure 7 Mass spectrum obtained with a quadrupole mass analyzer.

rapidly changed under computer control. By sequentially changing these applied potentials with a preprogrammed routine, different analyte ions can be sequentially selected for measurement. Each of these ions beams are integrated for a specific period of time, which can then be used for quantitation of the specific analyte elements.

In addition to providing higher sensitivity and precision, the peak-hopping mode of operation is generally considered to be the most desirable for quantitative analysis. It provides the most time-efficient approach for trace element analysis, because time is not wasted measuring regions of the spectrum that are not of interest. Peak hopping is also the method of choice for isotope ratio measurements with a quadrupole mass spectrometer.

4.3 Time-of-flight Mass Spectrometers

The time-of-flight instrument is a very simple mass analyzer that does not depend on a magnetic or electrostatic field to separate or isolate various m/z ions. Ions, which are accelerated to approximately constant kinetic energy, are allowed to drift down a flight tube 1–2 m in length. From the kinetic energy equation (Equation 2), velocities (v) of ions vary inversely with the square root of mass (m)

\[
KE = \frac{1}{2}mv^2
\]  

As they traverse down the drift tube, ions of different m/z reach the detector at the end of the tube at different times (i.e. are temporally resolved).

In order for this system to work, the ions must be pulsed into the spectrometer. As a pulsed group of ions enter the spectrometer, they are each time-resolved and measured as individual masses. Different m/z ions are separated in time by tens to hundreds of microseconds. Therefore, ions across the entire mass range are essentially measured simultaneously. Sequential pulsed groups of ions represent replicate measurements of the same sample.

Short analysis times are an important advantage of time-of-flight mass analyzers. Complete analysis of short-duration discrete transient sample introduction is possible. Therefore, in applications such as laser ablation or electrothermal vaporization, time-of-flight mass analyzers can be used with great advantage. In addition, this approach has the potential to provide much better precision in isotope ratio measurements.

On increasing the path length and focusing the kinetic energy of various m/z ions by using an ion reflector, which is essentially a repellent electrostatic well at the end of the flight tube, the direction of the drift of ions is reversed 180° (see Figure 8). By using this arrangement resolutions of the order of 3000 can be achieved.

4.4 Ion Trap Mass Spectrometers

An ion trap mass analyzer is based on principles somewhat related to a quadrupole mass filter. The system functions by trapping and storing a group of ions by means of an RF field in a space between a central doughnut-shaped ring electrode and two end-cap electrodes (see Figure 9). At certain RF potentials, all ions above a specific m/z are trapped within the space between the electrodes. As the RF and DC potentials are increased, ions of increasing

Figure 8 Diagram of a time-of-flight mass spectrometer.

Figure 9 Diagram of an ion trap mass analyzer.
m/z come into resonance with the trapping signal and are ejected through the end-cap electrode. These selected m/z ions are then detected by an electron multiplier. As with the quadrupole mass analyzer, the mass spectrum can be scanned by continuously varying the RF and DC potentials.

The ion trap normally operates at a higher working pressure than other mass analyzers (typically 10⁻³ mbar). This feature greatly facilitates the coupling of the ion trap to atmospheric pressure ion sources.

By careful selection of operating conditions, ions of a specific m/z can be rejected from the ion trap, while other m/z ions are preferentially retained. This feature is particularly valuable when the ion trap mass analyzer is used with inert gas (Ar) plasmas. The matrix element ions (Ar⁺) are continuously ejected from the trap while analyte ions are retained.

5 DETECTORS

The photographic plate with an ion sensitive emulsion was used extensively in the early days of mass spectrometry. It was used as the detector of choice for SSMS, where it offered the advantage of relatively uniform sensitivity for all elements, multimeasurement of multiple mass ions on a single aliquot of sample), and the ability to integrate a signal for a long period of time, which yielded high sensitivity resulting in very low detection limits. Unfortunately, the requirement of manual chemical development of the photoplate, coupled with limitations in precision (5–10%) and accuracy caused by plate inhomogeneity and the nonlinear response, reduced the popularity of this detector when more desirable alternatives were developed.

There are basically two types of detector that are employed with modern mass spectrometers: (1) the Faraday cup or analog detector and (2) the electron multiplier detector. The Faraday cup is the simplest of the two detectors. It is nothing more than a metal collector, coated with a low-work-function material such as BeO, GaP or CsSb, which converts an ion beam into an electrical current. A conventional low-noise DC amplifier then amplifies this electrical current. Advantages of the Faraday cup detector are its high stability, no mass discrimination and a virtually indefinite lifetime (no fatigue of the detector with use). Because only a few electrons are generated for each ion that collides with the coated collector, this detector is only suitable for high-intensity ion beam measurements, precluding its use for trace analysis.

The electron multiplier is used to measure the ion current of low-intensity ion beams. It consists of a series of dynodes with successively higher positive applied potentials. The dynodes are geometrically arranged so that an ion colliding with the first stage expels several electrons, which in turn are accelerated towards the second stage. When these electrons collide with the second dynode surface, more electrons are emitted which are accelerated towards the third stage dynode. A cascading effect results in a current at the final stage which has been multiplied by approximately a factor of 10⁶. This high gain and low dark current (without the requirement for detector cooling) makes the electron multiplier suitable for pulse counting applications. Electron multipliers have a finite operating life, which is proportional to the total ion flux or accumulated charge on the initial stage. Fatigue of the low work potential surface of the detector caused by high ion current exposure can also result in a loss of stability of the system. Therefore, care must be exercised in protecting the detector from overexposure. Specialized detectors which combine analog and electron multiplier devices can be used effectively to increase the dynamic working range of the spectrometer.

6 SAMPLE INTRODUCTION TECHNIQUES FOR INDUCTIVELY COUPLED PLASMA MASS SPECTROMETRY APPLICATIONS

Sample introduction techniques developed for atomic emission plasma spectrometry are directly applicable for ICPMS measurements. Three major types of samples are encountered: (1) solutions, (2) solids and (3) gases. Each of these will be discussed in some detail.

6.1 Solutions

Solutions are usually analyzed by a nebulization process, which converts the liquid sample into a finely divided aerosol (liquid droplets). This aerosol has a composition identical to the original sample. The droplets formed by the nebulization process are size classified by routing the gas stream containing the aerosol through a spray chamber or across an impinger bead. This process removes the larger size droplets and allows the finer ones to be transported via the gas stream to the plasma torch, where it is introduced into the plasma for further processing. The size classification process significantly improves the stability of the plasma by reducing “flickering” caused by the presence of large-size solvent droplets.

Several types of nebulizers are used depending on the specific requirements of the analytical application. The most common type is the pneumatic nebulizer, of which there are several different designs. All pneumatic
nebulizers share a common feature – they use the force of a flowing gas to create droplets from the liquid sample.

The crossflow nebulizer consists of two capillary tubes, usually made of glass or quartz, positioned at right angles to each other so that gas flowing through one capillary aspirates solution from the other capillary tube, generating an aerosol at the tip. As with other pneumatic nebulizers, the flowing gas that produces the droplets is used to transport the aerosol through the spray chamber and into the plasma.

A concentric-type nebulizer has similar performance characteristics to the crossflow nebulizer. It also consists of two capillary tubes, one that is slightly smaller is positioned inside the larger one in a coaxial configuration. Gas is directed through the outside capillary, aspirating sample solution through the center capillary. As with the crossflow, the aerosol is formed at the tip of the capillaries. Although both of these nebulizers will naturally aspirate liquid when gas is passing through them at an appropriate flow rate, pumping the solution using a peristaltic pump will usually produce a more uniform aerosol, while eliminating the possibility of variations in flow rate as a function of sample viscosity. Sample uptake rate for these types of nebulizers is typically about 1 µL min⁻¹. Typical detection limits for selected elements are listed in Table 3.

A special configuration of the concentric nebulizer, called the microconcentric nebulizer or the direct injection nebulizer, is used for the analysis of small quantities of sample. This nebulizer is mounted at the base of the plasma torch in such a way that aerosol droplets formed by the nebulizer are directly injected into the base of the plasma, without the use of a spray chamber. The diameter of the sample capillary is much smaller than that of a conventional concentric nebulizer, resulting in smaller size droplet formation and sample flow rates of the order of 100µL min⁻¹. In addition to low-volume sample consumption, when constructed from appropriate materials, this nebulizer provides for the direct analysis of corrosive substances.

A third type of pneumatic nebulizer is based on the design described by Babington. The principle of operation of this nebulizer is based on gas being forced through a small orifice over which the sample solution is passed. As the gas passes through the orifice, its shear force causes nebulization of the liquid at the orifice interface. This type of nebulizer requires a peristaltic pump to deliver the sample to the orifice, so it will not naturally aspirate sample. Although the measurement sensitivity of analytes determined using this nebulizer is similar to the other pneumatic nebulizers, it offers a significant advantage in not requiring sample to be processed through a small diameter capillary or orifice, precluding the possibility of partial clogging that can seriously affect the accuracy of the determination. Several variations of this nebulizer include the slot nebulizer, the cone spray nebulizer, the fritted disk nebulizer and the grid nebulizer. Each of these nebulizers has slightly different performance characteristics but they all function similarly.

Solid material in a suspended particulate form can be analyzed directly using the Babington-type nebulizer. This process is called slurry nebulization. As long as the maximum particle size is <8μm diameter, the particulate is quantitatively entrained in the aerosol droplets produced by the nebulizer. This aerosol is transported through the spray chamber and into the plasma. A suitable dispersing agent (surfactant) such as Triton-X100 is added to the sample to keep the particulate matter suspended. The primary advantage of this approach is to facilitate the analysis of solid materials without the need to perform chemical dissolution sample preparation, which may result in loss or contamination of analyte constituents.

In addition to pneumatic nebulizers, there are other types of nebulizer that are used for converting liquid samples to aerosols. One of the most popular is the ultrasonic nebulizer, which works on the principle that small quantities of liquid sample deposited on the surface of a high-frequency vibrating transducer crystal will produce an aerosol. The transducer is made to vibrate by the application of a 1-MHz RF signal from an oscillator. This type of nebulizer produces an aerosol with very fine-size droplets. Because of the fine particle size, the transport efficiency of this aerosol is very high, resulting in a complete elemental analysis on a very small quantity of sample. Sample is typically pumped onto the surface of the transducer through a capillary tube at the rate of about 100 µL min⁻¹.

Ultrasonic nebulizers are usually operated with a desolvating apparatus. This desolvation process consists of passing the gas stream, containing the sample aerosol, through a heated chamber to evaporate the solvent. The mixture of dry aerosol and vaporized solvent is then passed through a chilled condenser where the solvent

* Based on 30-µL sample volume.
is condensed and separated from the gas stream as a liquid. The dry sample particles in the gas stream are then transported to the plasma where they are vaporized. Because there is minimal solvent transported into the plasma after desolvation, more energy is available for dissociation and ionization of the analyte elements. Detection limits using this nebulizer are improved by a factor of 10–20 over those achieved by conventional pneumatic nebulization (see Table 3).

Another type of sample introduction device for the trace analysis of solutions is the electrothermal vaporizer. Aliquots of the sample are placed onto the surface of a metal filament, carbon rod or the interior surface of a graphite tube. An electric current is passed through the device, gradually heating it resistively to vaporize the solvent, leaving the sample residue on the surface of the device. The electrical current is then rapidly increased to heat the vaporizer to the boiling point of the constituents in the sample. The vaporized sample material is then transported in the gas stream flowing through the vaporizer into the plasma.

The instrument signal response produced by this technique is transient in nature. This means that a finite amount of analyte is introduced into the plasma over a specific period of time. During the period of time the analyte is resident in the plasma, the ions produced are sampled and the corresponding ion current is measured by the mass spectrometer. A plot demonstrating this transient signal is shown in Figure 10. Quantitation is performed by measuring either the peak height or the peak area of this transient signal. Peak area usually provides the best sensitivity and precision. Transient signal processing greatly complicates simultaneous multielement determinations. Because different analytes have a variety of analysis characteristics, such as variable volatility, it is often difficult to select a compromise set of operating conditions when processing transient signals.

High sensitivity is obtained by this technique, with detection limits approximately an order of magnitude superior to those obtained with ultrasonic nebulization (see Table 3). Typical size of sample deposited on the electrothermal vaporizer is in the 1–200-μL range, making this technique suitable for limited sample applications.

6.2 Solids

The direct introduction of solid sample into the plasma offers some significant advantages over the traditional chemical dissolution of solid materials followed by liquid sample introduction. For solid sampling techniques, minimal sample preparation is required. This approach not only saves time for the routine analysis of large numbers of samples, but it reduces the possibility of contamination of analyte species from other samples or from dissolution reagents. Because no solvent is present for direct solid analysis, molecular species such as ArO$^+$ are present at low concentrations and therefore are of minimal significance. Also, where appropriate for specific applications, some solid sampling techniques provide spatial resolution of the sample, providing lateral or depth profiling information.

In addition to the slurry nebulization technique previously described, solids can be introduced into the plasma by several techniques. These techniques include: direct insertion devices, electrothermal vaporization, arc or spark ablation, and laser ablation. Each of these techniques has unique characteristics that can solve specific trace analysis problems advantageously.

A direct sample insertion technique involves placing a powdered sample on a probe, which is inserted directly into the base of the plasma. The sample is ground sufficiently finely for milligram-size aliquots to be representatively sampled. The probe usually consists of a graphite rod with a cup formed at the end to hold the sample. Some types of apparatus employ a mechanical device to reproducibly insert the probe axially into the base of the plasma through the bottom of the plasma torch assembly. While the probe is being inserted, the sample is sequentially vaporized, decomposed, atomized and ionized. This is an extremely efficient means of introducing solid samples into the plasma.

Detection limits for this technique are easily achieved at the nanogram per gram level for most elements. Detection limits are quite variable depending on operating conditions, types of sample and element volatility. Often, thermochemical reagents are added to the sample to improve the analysis characteristics of refractory or carbide-forming elements such as aluminum, uranium and zirconium. Precision is of the order of 3–10% RSD. This relatively poor precision is attributed to sample inhomogeneity, which is exacerbated by the small sample size used by this technique.

Electrothermal vaporization, previously discussed under solution techniques, can also be used for direct
solid sample introduction. It is not a very popular technique because of the many problems associated with its utilization. Maximum sample size is restricted to about 1 mg. As with the direct insertion device, this size of sample presents problems in its ability to achieve statistically representative subsampling. This is reflected in the relatively poor precision (10% RSD) that can be obtained by using the technique. In addition to poor precision, poor accuracy is also characteristic of this technique because of nonrepresentative sampling for trace constituents and the lack of appropriate calibration standards.

Like the direct insertion device, electrothermal vaporization (for both liquid and solid samples) produces transient signals. It suffers similar difficulties to the direct insertion device. Coupling the electrothermal vaporization device with a time-of-flight mass spectrometer provides a very fast data acquisition technique that could produce many multielement measurements over the timeframe of the transient signal. This approach greatly improves the multielement analytical capabilities of electrothermal vaporization.

Arc and spark ablation consist of the application of an electrical current between the surface of an electrically conducting sample and a counter electrode. This ablation process produces a plume of volatilized and aerosol particulate sample that is transported by a carrier gas to the plasma for atomization and ionization. The main difference between an arc and a spark is the timescale of the discharge. The spark is a high-voltage (1 kV), low-current (mA), high-frequency discharge with a pulse width of between 1 μs and 1 ms, which consumes a small quantity of the surface of the sample (1% or less). Arcs, on the other hand, are low-voltage (40 V DC), high-current (10 A) discharges that are continuous in nature and can consume up to 50% of the sample. Depending on the operating conditions and the nature of the sample, material can be either directly vaporized or sputtered.

Since the spark technique works with a relatively large sample and operates in a continuous mode, a steady state rather than transient signal is obtained. This is analogous to constant introduction of a solution from a nebulizer, greatly simplifying data processing. This technique finds popular application in the trace analysis of pure metals and alloy samples. In addition, nonconducting materials, such as powdered geological rock samples, are analyzed by mixing with graphite and pressing into briquettes.

Finally, laser ablation has been developed into the most versatile solid sampling technique. Energy in the form of a focused infrared or ultraviolet laser beam is directed onto a solid sample surface, where a discrete portion is sputtered and vaporized. The sample specimen is housed in an enclosed cell with the laser beam focused on it through a window. As with the spark ablation system, the dry aerosol and/or sample vapor produced by the laser interacting with the specimen is transported to the plasma for ionization. By carefully controlling the operating characteristics of the laser beam (i.e. laser power, wavelength, repetition rate, etc.), the size and depth of the ablation crater can be controlled (5–60 μm diameter). This permits a spatially discrete amount of material to be sampled, resulting in a transient signal. By using an optical positioning apparatus, such things as grain boundaries or inclusions can be selectively analyzed. Repetitive sampling at a specific location can provide depth-profiling analysis of the sample.

Average composition or bulk analysis of the sample can be performed by rastering the laser beam across a fixed area of the sample surface. This approach provides an improvement in trace element sampling statistics and minimizes problems of sample inhomogeneity. Although the sensitivity for trace analysis by laser ablation ICPMS is not as good as that obtained by sample dissolution followed by pneumatic nebulization, the absolute detection limits are far superior.

Precision can be improved greatly by fusion of the sample with a flux such as lithium metaborate, forming a glass with a homogeneous composition and a flat surface for laser sampling. This approach also provides a convenient way of preparing calibration standards. A series of fusions are prepared with differing concentrations of the analyte elements. These fusions can then be used to produce calibration curves for quantitative analysis.

The laser ablation approach provides a powerful method for the analysis of solid samples requiring minimal sample preparation. It is especially useful for the analysis of materials that are difficult to dissolve, such as refractory ceramics or minerals. It also provides the unique ability to perform microspatial trace analysis of complex sample materials that are essentially impossible to analyze by other techniques.

### 6.3 Gases

Sample in the gaseous state is the easiest to introduce into the plasma for analysis, because it can be added directly to the plasma argon carrier gas. Generally the scope of analysis is limited to a single element or a small group of elements with similar chemical characteristics. Chemical reactions in solution are often used to generate analyte species in a gaseous form that are transported to the plasma from the reaction vessel. These reactions can be used to isolate the analyte species from the matrix of the sample and can also serve to provide a level of preconcentration.

The simplest chemical reaction is the reduction of mercury compounds to elemental mercury, which has a high vapor pressure at room temperature. Reducing
agents such as stannous chloride in hydrochloric acid or sodium borohydride quantitatively reduce dissolved inorganic species to the elemental mercury state. This mercury vapor is separated from solution and transported in the argon stream to the plasma for ionization.

Conversion of analyte species to molecular hydride compounds, which are volatile at room temperature, is also a suitable method for the determination of selected elements. Hydride generation is an effective technique for isolation and enhancement of the detection capability for elements such as antimony, arsenic, germanium, selenium, tellurium and tin. The most common reducing agent is sodium borohydride in acidic solution. The gaseous hydride compound is separated from the aqueous solution by sparging with argon gas or by using a gas–liquid separator. After separation, the hydride gas is transported to the plasma via the argon gas carrier stream, where atomization and ionization take place.

Gas chromatography coupled to an ICP has also been used for the determination of various volatile organometallic compounds. The compounds are separated in the chromatographic column and the effluent from the column is mixed into the argon gas carrier stream for introduction into the plasma. This approach is particularly important for speciation applications.

7 COMPARISON OF CHARACTERISTICS OF INDUCTIVELY COUPLED PLASMA MASS SPECTROMETRY WITH INDUCTIVELY COUPLED PLASMA ATOMIC EMISSION SPECTROMETRY

The ICP has been effectively used as an atomic emission spectroanalytical source for trace multielement analysis for many years. The configuration and operating characteristics of the plasma are essentially identical regardless of whether it is being used for inductively coupled plasma atomic emission spectrometry (ICP-AES) or atomic mass spectrometry (ICP-MS). Both techniques offer advantageous characteristics for analytical applications. Because the plasma is essentially the same, the sample introduction techniques described above can be effectively used by either approach.

The primary difference between the two techniques is that with ICPMS ions generated by the high-temperature plasma are sampled with an extraction cone and measured by the mass spectrometer. Comparatively, with the ICP-AES technique, atoms and ions in the high-energy plasma are excited and emit optical radiation, which is focused with a lens or mirror onto the entrance slit of the spectrometer, where specific characteristic wavelengths are isolated and measured.

Although both techniques provide the ability to determine essentially all elements in the periodic table, ICPMS provides the additional capability of measurement of specific stable isotopes. Both techniques provide a wide linear dynamic measurement range, covering three to five orders of magnitude. Use of multiple emission wavelengths with the ICPAES technique allows the analyst to select the spectral line with the most appropriate intensity to provide optimal signal-to-noise ratios (i.e. low-intensity lines for measurement of high concentrations and high-intensity lines for measurement of low concentrations). Although this approach is usually not available with ICPMS (relatively few uninterfered isotopes are available for analytical measurements), sophisticated multiple detector instrumentation permits a wide dynamic range signal to be processed, which extends the working range over many orders of magnitude (eight or more). With either technique, concentration of elements ranging from major components of the sample to ultratrace constituents can be measured essentially simultaneously on a single sample aliquot. Generally detection limits for ICPMS (1–50 ng L⁻¹) are one to two orders of magnitude superior to those obtained for ICPAES.

A serious problem with ICPAES is the potential for spectral interference, which can have a serious impact on the accuracy of the analysis. Spectral overlap between high-concentration components in the sample and the trace analyte emission lines can preclude or degrade the quality of analytical measurements. In addition, molecular band emission spectra and continuum background radiation can have a serious impact on accuracy and detection limits. The relatively simple mass spectrum obtained with inorganic mass spectrometry with very low backgrounds, including the low prevalence of polyatomic molecular species and the relatively few isobaric interferences, can be alleviated with the use of high-resolution mass spectrometers, mitigating a similar problem in ICPMS.

The combination of high sensitivity (low detection limits), fewer interferences, excellent accuracy and good precision, combined with the ability to make independent stable isotope measurements, makes ICPMS the most powerful tool for trace elemental analysis. The use of numerous sample introduction techniques provides the versatility to solve most of the analytical chemistry problems facing the modern analytical chemist.

With the separation of two of the three stable isotopes of neon by Sir J.J. Thomson in 1913, mass spectrometers have continued to be the instrument of choice for measuring ratios of isotope abundances. The first magnetic sector mass spectrometer specifically dedicated to this task was designed by A.O. Nier in 1947 and featured simultaneous collection of ion currents. Many diverse instruments have evolved from this design. Decades of development of sample preparation techniques have realized isotope ratio data from many elements in solids, liquids, and gases. Coupling of devices such as gas chromatographs, combustion apparatus, and laser probes to mass spectrometers in concert with computer control, have realized features such as unattended operation, compound-specific isotope analyses and isotopic data spatially resolved over distances of a few micrometers on solid surfaces.

Today, applications of isotope ratio mass spectrometry (IRMS) embrace many disciplines with topics such as paleoecology, food adulteration, paleoclimatology, migration of birds and animals, pollutant tracing, ore and oil deposits, meteorology, energy expenditure of animals, including astronauts, and the origin of the universe.

1 INTRODUCTION

The term ‘isotope’ is derived from the Greek words isos and topos to denote the ‘same place’ in the periodic table. Thus, isotopes are atoms whose nuclei contain the same number of protons but different numbers of neutrons. Isotopes are designated by a superscript which denotes the nucleon number (protons plus neutrons), placed to the upper left (upper right in earlier literature) of the symbol for the element, e.g. $^1\text{H}$, $^2\text{H}$, $^3\text{H}$ for the three isotopes of hydrogen. In contrast to the practice with other elements, hydrogen’s isotopes have been dubbed hydrogen (or protium), deuterium, and tritium and are often given the symbols H, D, and T.

Only 21 elements have one stable isotope, whereas element 50, Sn, possesses the most, 10. Of nearly 400 naturally occurring isotopes, 271 are stable or have half-lives many orders of magnitude larger than the age of our Earth. Their existence and abundances are determined by nuclear stability principles, including the Oddo–Harkins classification (Table 1) based on even versus odd numbers of protons and neutrons. Isotopes differ in fundamental physical properties such as mass, nuclear spin, and nuclear stability. Although isotopes of a given element participate in equivalent chemical reactions, they do so with different rate constants because of differences in isotopic vibrational frequencies and zero point energies of molecules. Many physical processes are also mass dependent and hence isotopically selective.

Alteration of isotope abundances is termed isotope fractionation or an isotope effect. These terms have been used interchangeably but there is a tendency to identify
the former with differences in isotope compositions among components in a system and the latter with a mass-dependent process.

The term ‘isotope fractionation factor’, $\alpha$, is defined by Equation (1),

$$
\alpha_{A-B} = \frac{R_A}{R_B}
$$

where $R$ is the ratio of the heavy to light isotope abundances (D/H, $^4$He/$^3$He, etc.) in compounds A and B. The species A and B may also be different phases of the same molecule, such as liquid and gaseous H$_2$O.

Because of the difficulty of determining absolute isotope abundances, relative abundance ratios are reported using $\delta$-values (historically called ‘del’ or ‘delta values’ with a decided preference for the latter to be consistent with the Greek symbol). The $\delta$-values for the stable isotopes of hydrogen are defined (Equation 2) as

$$
\delta \text{D (in parts per thousand)} = \left( \frac{[\text{D/H}]_x}{[\text{D/H}]_s} - 1 \right) \times 1000
$$

where $x$ and $s$ denote the sample and an internationally accepted standard, respectively. The term D/H is the ratio of the numbers of deuterium and protium isotopes. The scale is in parts per thousand, ‰, and written as ‘permil’, ‘per mille’, and other language-dependent alternatives. Positive and negative $\delta$-values mean that the sample is enriched and depleted, respectively, in the heavier isotope, relative to the standard.

There are similar $\delta$-value definitions for other elements; for example, $\delta^{18}$O in terms of $[^{18}$O/$^{16}$O], $\delta^{34}$S in terms of $[^{34}$S/$^{32}$S], etc.

The $\delta$-value comprises a ratio of ratios and is consistent with the measurement strategy of IRMS. The objective is to compare a sample with a calibrated laboratory standard under identical conditions so that measurement biases cancel in the numerator and denominator of the $\delta$-value definition. The precision of $\delta$-value determinations can be better than $\pm1.0$‰ for hydrogen and better than $\pm0.1$‰ for other elements. For agreement among different laboratories, a variety of reference materials have been prepared and distributed by the National Institute of Standards and Technology (NIST) in the USA and the International Atomic Energy Agency (IAEA) in Vienna. Most researchers use these reference materials to calibrate working standards and to ensure that data are reported on scales consistent with other laboratories.

The fractionation factor is related to $\delta$-values by Equation (3):

$$
\alpha_{A-B} \approx \frac{1000 + \delta_A}{1000 + \delta_B}
$$

Isotope fractionation can be identified with reversible exchange reactions and unidirectional kinetic effects. An exchange reaction can be generally written as Equation (4),

$$
aA_1 + bB_2 \rightleftharpoons aA_2 + bB_1
$$

where A and B are as defined above, $a$ and $b$ are the number of moles of A and B, and subscripts 1 and 2 denote the lighter and heavier isotopic species, respectively. The equilibrium constant for this reaction is given by Equation (5):

$$
K = \frac{(A_2/A_1)^a}{(B_2/B_1)^b}
$$

Bringing compounds together does not ensure that exchange will occur or that isotopic equilibrium will be established. Equilibrium for oxygen isotope exchange between CO$_2$ and H$_2$O is realized in a few hours at room temperature, whereas oxygen isotope exchange between SO$_4^{2-}$ and H$_2$O has a half-time of $10^5$ years under ambient neutral solution conditions. The heavier isotopes are usually favored in the compound in which the element is in the higher valence state (lower zero-point energy) and in the more condensed phases. Using methods of statistical thermodynamics, isotopic partition function ratios can be calculated and used to evaluate equilibrium constants as a function of temperature. Additional to their importance in nature and commercial isotope enrichment operations, exchange reactions are used in analyses of isotope compositions. For example, O- and H-isotope compositions of water can be based on measurements with CO$_2$ and H$_2$ that have been equilibrated with H$_2$O samples.

A kinetic isotope effect (KIE) is identified with a unidirectional process and is expressed in terms of two competing reactions (Equation 6):

$$
A_1 \xrightarrow{k_1} P_1 \quad \text{and} \quad A_2 \xrightarrow{k_2} P_2
$$

where A and P correspond to reactant and product. Although the term has been used with a variety of physical, chemical, and biological conversions, in a stricter sense it is defined as the ratio of the isotopic rate constants $k_1/k_2$ in one step of a chemical reaction. Lighter isotopic bonds have higher vibrational frequencies corresponding to higher ground-state energies and therefore lower

energy requirements for rupture. Transition state theory provides a basis for calculation of \( k_1/k_2 \) values.\(^8\)

As an isotopically selective reaction proceeds, the isotopic compositions of components in the system change depending upon whether it is open or closed to reactant and product. For a one-step first-order process illustrated in Figure 1, the equations derived by Lord Rayleigh for distillation of mixed liquids can be applied. With the lighter isotope favored in the product, the remaining reactant becomes more relatively enriched in the heavier isotope as the conversion proceeds. The product formed at any instant has a \( \delta \)-value which is approximately \( [(k_1/k_2) - 1] \times 10^3 \) lower than that of the residual reactant. The instantaneous curve in Figure 1 would apply to a system with the product escaping upon its formation. If all the product is retained in the system, its isotopic composition at 100% conversion is the same as that of the initial reactant as shown by the total product curve in Figure 1.

Many approximations to the curves in Figure 1 have been derived.\(^9,10\) For example, changes in the isotopic composition of the remaining reactant can be described by Equation (7) or Equation (8),

\[
\frac{A_1}{A_2} = \left( \frac{A_1}{A_2} \right)_{\text{initial}} f^{(\alpha-1)}
\]

\[
\delta = \delta_{\text{initial}} f^{(\alpha-1)}
\]

where \( f \) is the fraction of unconverted reactant.

Mass-dependent isotope fractionation is also associated with physical phenomena including diffusion, evaporation, melting, absorption, heat capacity, and crystallization. Not only can isotopic abundance data be used to better understand these processes, but the fractionation may be relevant to the design of instrumentation used to measure isotope abundances (sections 2.3.2 and 2.4). Stable isotope abundances of an element may be also substantially altered by nuclear reactions (section 7).

In principle, there are many ways to determine isotope abundances. Relatively simple concepts such as density and heat capacity determinations are difficult to effect in practice for many reasons including the requirement of very pure substances. As molecular vibrational and rotational frequencies are isotopically dependent, some applications such as \(^15\)N-labeling studies routinely use optical emission spectroscopy.\(^11\) Nuclear magnetic resonance (NMR) spectroscopy has the distinct advantage of being able to determine the isotope compositions of specific sites in molecules. Although there has been considerable success with D/H measurements,\(^12\) many environmentally important isotopes such as \(^16\)O and \(^32\)S have zero nuclear spin and therefore are not NMR responsive.

The instrument most widely used for isotope abundance determinations is the mass spectrometer. Historically, the challenge was the discovery of stable isotopes with Sir J.J. Thomson separating two of the three stable isotopes of neon in his positive ray apparatus in 1913.\(^13\) A few years later, Aston\(^14\) and Dempster\(^15\) built improved mass spectrographs to discover and determine the abundances of many isotopes. Aston identified the third stable isotope of He and in his lifetime discovered 212 naturally occurring isotopes.\(^16\)

From the principles of isotope fractionation outlined above, it is seen that it is highly desirable to measure ratios of isotope abundances (referred to as isotope ratios) in specimens. The first magnetic sector mass spectrometer specifically dedicated to isotope ratio determinations was a 60° magnetic analyzer (MA) designed by Nier.\(^17,18\) Many diverse instruments have evolved from this design.\(^19–21\)

Prior to the 1960s, most stable isotope mass spectrometers were constructed by individual researchers throughout the world. Understandably, current commercial units are expensive because of the overhead requirements for manufacturing such specialized equipment. The financial stability of companies willing to undertake the task was constantly challenged and most changed ownership over time. Finnigan-MAT, Germany (Atlas-MAT), and Vacuum Generators, UK (Micromass, Fisons), account for the bulk of the installations globally. Earlier instruments in the USA included many produced by Nuclide and a few solid source units by AVCO. In other countries, instruments were offered by Thomson (France) and Hitachi (Japan). Institutions in the former USSR had mass spectrometers produced within the Soviet Academy of Science. Europa Scientific, UK, which emerged in recent years, has specialized in continuous flow (CF) instruments (section 3).

Specific commercial instruments will not be discussed as such but rather the fundamental concepts underlying components of isotope ratio mass spectrometers.

**Figure 1** Isotopic behavior of components in a one-step first-order reaction with a KIE \( k_1/k_2 \).
2 BASIC MAGNETIC SECTOR ISOTOPE RATIO MASS SPECTROMETER

A magnetic sector IRMS consists of a vacuum system, source, MA region, ion collector assembly, and ion detection electronics.

2.1 Vacuum System

Flight tubes of mass spectrometers are operated at high vacuum (~10⁻⁸ torr) to minimize collisions of the ion beams with ambient molecules. (1 torr is approximately the pressure due to a 1 mm column of mercury and equates to 133.3 Pa or 1.3 mbar.) Such low pressures can be realized with a number of pumping systems.²²⁻²⁵

Most systems require a roughing pump. Roughing pumps are usually oil-sealed mechanical units capable of realizing pressures in the 10⁻³ torr region. During their rotation, a portion of low-pressure gas in the system is trapped at its inlet, compressed, and expelled to the atmosphere (Figure 2a). A trap (e.g. molecular sieve) is placed at its input where it serves as a fore or backing pump for high-vacuum pumps.

There are four general types of high-vacuum pumps which operate on different principles: vapor-stream or diffusion pumps; turbo-molecular pumps; chemical/ion pumps; and cryogenic pumps. Diffusion pumps have boiling heavy liquid reservoirs (Figure 2b). The vapor is directed through jets to impart momentum to molecules in the system so that they move towards the inlet of the fore pump. Subsequently, the vapor is condensed by a water-cooling jacket and returned to the reservoir. The working fluid must be thermally stable, chemically nonreactive, and have a low vapor pressure. Mercury used in earlier systems required a liquid N₂ trap at the pump's inlet to prevent its condensation in the mass spectrometer. Since the early 1980s, polyphenyl ethers have been used successfully in diffusion pumps and do not require liquid N₂ trapping.

Turbo molecular pumps (Figure 2c) consist of a metal housing containing a rotor and stator with obliquely slotted discs. They can be considered as turbine engines operating in reverse. The rotor is driven at speeds as high as 60,000 rpm and molecules are forced to each end of the port. Stator–Rotor disc pairs act as pumping stages in series so that gas in the system at pressures of the order of 10⁻⁴ torr is compressed to 10⁻² torr and introduced to a backing pump. The pressure ratio increases with the molecular weight of the gas so pumping of H₂ and He is much slower. Lubrication of the rotor bearings is a challenge. The use of oil introduces organic vapors and cooling of the bearings is necessary. The situation has been improved by using ceramic bearings and lubrication can be avoided entirely by magnetic levitation of the rotor.

Chemical pumps form a chemical bond between the pumped gas and an absorbent. In a typical ion pump (Figure 2d), a stainless steel grid is placed between two titanium cathode plates. A potential difference of about 3 kV is applied to the electrodes which sets up a cold-cathode discharge. Positive ions impacting on the cathode sputter titanium onto surfaces of the anode grid. A magnetic field (~0.1 T) normal to the electrode sandwich causes electrons to move in spiral paths, thereby increasing the ionization efficiency. Ion pumps are quiet, have low power consumption and, after starting, do not require a backing pump. The ion current is a measure of the pressure, whereas other systems require a vacuum gauge. The pump fails when the cathode has become saturated with buried atoms so the lifetime (order of 5 years at 10⁻⁸ torr) is inversely proportional to the pressure. The anode and cathode can be electrolytically cleaned and reused a few times. During operation, buried atoms can be released from the cathode with subsequent bombardment and chemically inactive gases such as Ar are particularly prone to release.

In one version of a cryogenic pump or cryopump, an internal element cooled by circulating liquid He, called a cryopanel, condenses gases in the system. Effective pumping requires that the built-up solid molecular layers possess a low vapour pressure and high sticking probability for incident molecules. The pumping element may be enclosed in a liquid N₂ cooled baffle so that it does not receive radiation from the inner walls of the system (Figure 2e). The cryopanel can be regenerated by warming and pumping with a fore pump. A fore pump is also used before starting the cryopump, to avoid a thick condensation layer from pumping air at atmospheric pressure. Cryopumps have much higher speeds for a given size in comparison to other high-vacuum pumps. The species He, H₂, and Ne are difficult to condense. Steps may be required to isolate the mass spectrometer from vibrations caused by the circulation of liquid He.

Sorption pumps (Figure 2f) differ from chemical and cryopumps in that molecules are sorbed as a monolayer on charcoal or zeolite (molecular sieve) pellets usually immersed in a liquid-N₂ trap. The sorbed molecules are released by mild heating. These pumps can be used in place of mechanical backing pumps during the start-up of ion pumps, thereby eliminating organic contamination in systems.

Realizing high vacuum is not only dependent upon the pumping system but also upon the plumbing. Piping to pumps should have diameters as large and lengths as short as possible. Mass spectrometer tube assemblies are usually constructed with nonmagnetic stainless steel and inert gas-welded joints. The latter should be constructed so that pockets cannot form, where trapped gases are...
difficult to pump out. Coupling of sections is usually done with flanges with knife-edge annuli pushing into copper gaskets. If reactive gases such as SO$_2$ are involved, gold O-rings compressed between flat flanges can be used. For flanges that are frequently uncoupled, Viton® O-rings are another possibility.

Electrical insulators inside the source and collector as well as feedthroughs should be made of glass or ceramic
materials, rather than of polymers which may outgas over long periods.

Dependent upon the sample introduction system, pressures in the source region can greatly exceed \(10^{-8}\) torr. Hence, it is desirable to separate it from the flight tube and collector; the only necessary connection being the source exit slit. In this way, the former may be pumped with a fast system such as a turbomolecular pump and the latter maintained at \(10^{-8}\) torr with perhaps a modest ion pump.

2.2 Source

Mass spectrometer sources serve two functions: generation of ions from samples in solid, gas, or liquid states; and formation of an ion beam that is directed down the flight tube into the analyser region. Many combinations of nonmagnetic stainless steel plates with slits or other features have been used to form ion beams.

The ionization region is usually placed at a potential of 2–10 kV above ground. A variation of a Nier-type source is shown in Figure 3.\(^{26}\) The plate below the ionization region is termed the drawing out plate (DOP) and its potential is such that some equipotential surfaces curve upwards into the ionization region. The corresponding electric field lines curve inwards as they go downwards towards the slit of the DOP. Thus ions from a cross-sectional area in the ionization region larger than that of the DOP slit, pass through the latter.

Two half-plates below the DOP are usually at slightly different potentials to bend the ion beam so that transmission through the grounded exit slit is maximized. The DOP–half-plate combination may have simple slits or shaped elements such as the Nier thick lens shown in Figure 3.

In simple designs, consecutive grounded plates with different slit widths may serve to geometrically focus or collimate the ion beam. In other designs, there may be a collimator plate with slit held at a potential intermediate between the half-plates and grounded exit slit (Figure 3).

Another option shown in Figure 3, is a pair of \(z\)-focus plates which reduce spreading of the length of the ion beam’s cross-section. Slightly different potentials on these plates can shift the ion beam along the exit slit length-wise (referred to as tilt) to maximize transmission.

To a first approximation, an ion current leaving the source is proportional to the flux of the corresponding molecular species entering the ionization region. Change in the proportionality constant with sample flux is referred to as nonlinearity. A perfectly linear source is unobtainable because of phenomena such as space charge distribution which depend on ion density. Nonlinearity in IRMS is not limited to the source, and isotope abundance data should be obtained with the same major ion current for all samples.

In the source, an ion acquires kinetic energy given by Equation (9):

\[
Vq = \frac{1}{2}mv^2 \tag{9}
\]

where \(V\) is the potential difference between the position where the ion is formed and the exit plate which is usually at ground, \(q\) is the charge, \(m\) is the mass, and \(v\) is the speed.

2.3 Gas Source

Gases may be ionized in a number of ways (e.g. ultraviolet radiation), but the preferred method is by electron ionization (EI) (also termed electron bombardment) because of its higher efficiency.

2.3.1 Electron Impact Assembly

A typical EI assembly developed by Nier and others.\(^{17,18}\) is shown in Figure 4. Electrons emitted by a filament are accelerated by a potential difference of 50–100 V and pass as a beam into an ionization box, referred to as the case or shield. Gases passing through the opening shown at the top of the case in Figure 4, collide with the electron beam and are ionized. The electron beam exits the case and enters a trap held at a potential of about 20 V above that of the case. The filament electronics supply uses the trap current (~200 \(\mu\)A) in a feedback loop to control the filament current and hence electron emission.

During electron bombardment, the majority of the produced ions are positive. Not only are valence electrons knocked from molecules, but ion fragments are also produced dependent upon the electron energy. Increasing the potential difference between the filament and case increases the total ion current through a maximum and also tends to produce more fragments, as shown for GeF\(_4\).
in Figure 5. Interestingly for GeF₄ and other fluoride gases such as SiF₄, SF₆, SeF₆, and TeF₆, removal of one electron is much less probable than release of a F atom. With SO₂, the maximum SO₂⁺ production is of the order of 60% of the total ions. As by suitable choice of electron energy the SO⁺ production can exceed 40%, some workers use that species for sulfur isotope abundance determinations especially if the IRMS has low resolution.

Application of a magnetic field along the direction of the electron beam causes electrons diverging from the path to follow tight helices. This can improve the ionization efficiency by a factor of 10 and the narrowing of the beam results in ions being formed more or less along an equipotential surface. The ions leave through a slit shown at the bottom of the case in Figure 4 along the electric field lines created by the DOP (section 2.2). Some EI assemblies feature a repeller above the electron beam which can be adjusted a few volts positive or negative with respect to the case to maximize expulsion of ions.

For some gases such as UF₆, adsorption and precipitation of solids on the inner walls of the case have been addressed with a more open case construction. Reactions between molecules and ions may require special attention. For example, during EI ionization of H₂, H₃⁺ ions are formed which are not resolved from the HD⁺ ion beam in a typical low-resolution IRMS. The [H₂⁺]/[H₃⁺] value has a linear dependence on [H₂⁺] and hence the H₂ pressure but also varies with the repeller voltage. Through measurements at different pressures, the H₂⁺ contribution can be determined for the particular operating conditions.

Because the EI source is ideally suited for gases and even vapors emitted from solids, it is the most widely used in mass spectrometry (MS). It has also been modified for special purposes such as an open ion source in space flights.

2.3.2 Gaseous Sample Introduction

A distinct advantage of a gas source IRMS is sample introduction without breaking the vacuum. Samples should be prepared as pure as possible. In some cases, certain impurities cannot be tolerated. For example, N-isotope analyses with ¹⁴N²⁺ and ¹⁴N¹⁵N⁺ are adversely affected by even small amounts of CO₂ or CO because of ¹²C¹⁶O⁺ and ¹³C¹⁶O⁺ contributions at masses 28 and 29. A further requirement might be isotopic consistency of some elements in the gas being analyzed. For S-isotope analysis of SO₂, ³⁴S¹⁶O₂⁺ and ³²S¹⁸O¹⁶O⁺ and other species are unresolved at mass 66. Hence, the oxygen isotope composition of SO₂ should be invariant from sample to sample.

In some applications where high sensitivity is required, an IRMS is operated in the static mode. The entire gas sample is admitted and all pumping of the mass spectrometer suspended. The minimum amount of gas required depends upon its ionization efficiency, the percentage of produced ions reaching the collector (transmission efficiency), and the mode of ion detection. Measurements have been made with fewer than 10⁶ atoms of a given isotope.

It is more usual for a gas-source IRMS to be operated in the dynamic mode. The gas is introduced through a leak and the mass spectrometer continuously pumped.

Gas admission to the source through a pin-hole leak is described by Graham’s law of diffusion whereby the
flow is proportional to the inverse of the square root of the mass. This is known as molecular or effusive flow and the mean free path of the molecules is many times greater than the diameter of the hole. It also happens that unionized gas diffuses effusively out of the ionization chamber. Hence there is a cancellation of mass discrimination effects and the ion currents leaving the source closely represent the isotopic composition of the sample. The disadvantage of a molecular leak is the change in isotopic composition of the sample over time. This can be minimal if a small fraction of a given sample is consumed during analysis. It is more challenging to maintain reference gas reservoirs which must be large and frequently monitored isotopically. The low pressure differential across a molecular leak realizes its main advantage, small sample requirement.

The alternate extreme is a long capillary leak (order of 0.1 mm internal diameter by 0.5 m length) with the mean free path of molecules in the sample being many times shorter than the dimensions of the leak. The flow is termed viscous and is independent of mass of the molecules (Poiseuille’s law). In practice, passage of gas through a capillary is complicated with viscous flow on the reservoir end, molecular flow into the ionization chamber, complex flow between the ends, and back-diffusion. The situation is improved by careful pinching of the capillary close to the end entering the mass spectrometer and having a sample pressure of ~20 torr. Conditions between the molecular and viscous extremes are termed ‘Knudsen flow’, in recognition of his mathematical expressions relating flow to pressure, temperature, mass, and tube dimensions. As the mass dependence of flow is highly dependent upon sample pressure, this region should be avoided.

In traditional IRMS, the pressure requirement for viscous flow limited the minimal sample size to ~1 mg of the element of interest. For some studies such as trace gases in ice, this is unsatisfactory. There have been moderately successful attempts to carry out traditional IRMS with smaller samples. One approach is the use of very small sample reservoirs (~500 µL). As the flow conditions depend on the total pressure, viscous flow can be maintained for small samples by additions of inert gas. Higher-sensitivity detectors are then used to measure the smaller ion currents produced from the sample gas.

Another approach has been to freeze the prepared gas into a microcontainer and use a pusher gas to act as a piston to introduce the sample into the mass spectrometer. The challenge is to realize isotopic analyses of the sample before there is substantial mixing with the pusher gas. The latter can be the same chemical compound as that being analyzed. Then the change in isotope composition of the gas mixture with time can be used to more accurately calculate the isotope composition of the sample.

To minimize problems associated with source nonlinearity, it is desirable to compare a sample and reference gas under identical conditions. For this purpose, dual-inlet (DI) systems were developed in the 1940s. In Figure 6, the central valves are cross-connected so that one pair is open while the other is closed. In this way, the sample gas can enter the ion source while the reference gas is pumped away by a waste line, or vice versa. There are various valve designs including electromagnetically operated ground glass joints and pneumatically actuated Nupro valves. Switching can also be accomplished by alternately blocking the low-pressure ends of the leaks with Teflon® diaphragms or modified Nupro valves.

Although pressure builds up in the blocked capillary, the increase in flow upon opening subsides within a few seconds. This approach does not require a waste line.

The pressures of the reference and sample gas are matched by varying the volume of the stainless steel bellows in Figure 6, either manually or by stepper motors. To accommodate small quantities of gases, the sample bellows is smaller. As bellows have a limited compression distance, a cylindrical block inserted in the sample bellows provides a larger fractional range of volume change. In an earlier environmentally questionable design, columns of Hg were raised or lowered in vertical glass tubes to adjust the pressures. The U-tube Hg manometers used to measure sample pressure have been replaced today by electronic capacitance manometers.

If sample size is not limited, DI/IRMS is the instrument of choice because it realizes the best precision. However, there is the requirement that gases for analyses be prepared in very pure form without isotope fractionation. This can prove time-consuming and involve expensive reagents.

2.4 Thermal Ionization Source

During heating of a salt-coated filament, positive and negative ions may be emitted as well as neutral particles. This has been termed thermionic emission surface ionization or thermal ionization (TI), most frequently implemented as thermal ionization mass spectrometry (TIMS).
2.4.1 Thermal Ionization

The efficiency of the emission of positive ions has been theoretically described by the Langmuir–Saha equation,

\[ N^+ = N_0 \exp \left( \frac{W - eIP}{kT} \right) \quad (10) \]

In Equation (10) \( N^+ \) is the number of positive ions, \( N_0 \) is the number of neutral particles, \( e \) is the electronic charge, \( W \) is the work function of the filament material in eV, \( IP \) is the ionization potential of the species being ionized, \( k \) is the Boltzmann constant and \( T \) the absolute temperature, \( kT \) being in units of electron volts.

For negative ions, Equation (10) is altered to Equation (11),

\[ N^- = N_0 \exp \left( \frac{EA - W}{kT} \right) \quad (11) \]

where \( EA \) is the electron affinity of the species in eV.

2.4.2 Filament Design

Using typical pure metal filament materials, there are only a few cases for which the exponent in Equation (10) is positive (Figure 7). Easily shaped platinum with the highest work function, is used extensively, the drawback being its low melting point. Zone-refined rhenium with a slightly lower work function but much higher melting point is the material of choice. It turns out that many elements, notably the alkalis, alkaline earths, rare earths and transuranium elements, can be successfully run by positive ion thermal ionization mass spectrometry (PTIMS).\(^{35}\)

Filaments are usually spot welded to stainless steel or other metal posts set in a ceramic button (Figure 8). Alignment pins on the button are used to plug the filament assembly into the ionization chamber of a TIMS (Figure 3). With single filaments, higher temperatures promote ion production but the sample is more rapidly evaporated. The evaporation and ionization processes can be separated by employing two filaments in close proximity (Figure 8).\(^{43}\) One filament, coated with the salt, is heated at a lower temperature and evaporates the sample in a controlled manner. The second hotter bare filament ionizes the evaporated species. A further development is the triple filament source in which the two filaments coated with sample are placed symmetrically about the central ionizing filament (Figure 8). For some salts, a reference and sample can be placed on the two ionization filaments and alternately analyzed in the double filament mode.

Figure 7 Ionization potentials, work functions, melting points, and electron affinities for selected elements and molecules.

Figure 8 Single-, double-, and triple-filament assemblies.
It turns out that Equations (10) and (11) are at best, qualitative guidelines. Boat-shaped single filaments or even placing of sample in a dimple\(^ {45}\) on a single filament can achieve ionization efficiencies approaching those of triple-filament assemblies. Further, a variety of additives such as silica gel/H\(_3\)PO\(_4\)\(^ {45}\) have enhanced ionization for elements with high ionization potentials (>7 eV)\(^ {20,21}\).

A disadvantage of TIMS is the mass-dependent fractionation occurring during evaporation/ionization\(^ {20,21,46}\). To a first approximation, the evaporation rate is proportional to the inverse of mass and the change in isotopic composition of remaining sample over time can be described by a Rayleigh distillation equation (Figure 1). One approach is to attempt to analyze all of the sample but this could require several hours. In practice, the phenomenon is quite complex and various equations have been derived to extract true isotope abundance ratios from temporally varying ion currents\(^ {46,47}\).

Mass-dependent fractionation may be reduced through the use of multiple filaments. For example, when \(^6\)Li\(^+\) and \(^7\)Li\(^+\) are generated with a single filament, the kinetic effect is \(7^{1/2}/6^{1/2}\). However, when LiNO\(_3\) is evaporated intact from a sample filament and the molecules dissociated to produce Li\(^+\) by the ionization filament, the mass dependence ratio is smaller, \(69^{1/2}/68^{1/2}\)\(^ {48}\).

To minimize the effects of instrumental nonlinearity (section 2.2), the major ion current should be maintained as constant as possible throughout a run and from sample to sample. This also requires that filament construction and sample deposition be reproducible.

Along with its drawbacks including the time requirements for sample preparation and ion current measurement, TIMS has many favorable features. The ions are nearly monoenergetic (~0.2 eV spread) and samples in the range \(10^{-6}-10^{-9}\) g can be analyzed. A large number of elements can be analyzed by PTIMS or NTIMS and some by both. Measurements of two elements with one sample loading is also possible\(^ {49}\).

A disadvantage is the requirement to open the instrument to insert the filament assembly. Through the use of a gate valve above the source housing, it is possible to expose only a small volume to the atmosphere (Figure 9). The filament assembly attached to a probe can be pushed into and pulled from the ionization chamber. In Figure 9, the probe is just above its position during operation. For removal:

1. pull probe outwards until filaments are just above the gate valve;
2. close the gate and fore line valves;
3. open the bleed valve and complete withdrawal.

**Figure 9** Vacuum lock for introducing and removing filament assemblies from a TIMS with minimal temporary reduction of vacuum. It is similar to a device on older AVCO instruments.

For insertion:

1. push probe inwards until filaments are just above the gate valve;
2. close bleed valve and open fore line valve;
3. at lowest fore line pressure, close fore line valve;
4. open gate valve and push probe inwards until the filament is in the ionization chamber.

To minimize opening of the source region, most commercial TIMSs are equipped with a rotatable carousel (Vacuum Generators, UK) or ferris wheel or turret (Finnigan MAT 262) on which up to 21 filament assemblies can be attached.

2.4.3 Isotope Spiking

Spiking is the addition of known amounts of one or more isotopes of the element of interest to a sample. One application is the determination of low concentrations of elements in a specimen. When the spiked sample is analyzed isotopically and the known spike additions accounted for, the numbers of each isotopic species in the specimen can be calculated\(^ {20,21}\). This technique is called isotope dilution mass spectrometry (IDMS)\(^ {50}\).

A double spike is a known combination of two separated isotopes and its addition to a sample can be used to calculate systematic discrimination during isotope analysis\(^ {51}\). Double spiking has become routine for many elements in TIMS. Addition of the spike at an early stage of chemical digestion of samples can also account for mass-dependent isotope fractionation during extraction of the element. For this reason, spiking should be used more frequently with other IRMS methods.
2.5 Analyzer Region

A magnetic field exerts a force on a moving ion which is perpendicular to both its velocity and the magnetic field lines (Equation 12):\[ \mathbf{F} = q\mathbf{v} \times \mathbf{B} \] (12)

where \( \mathbf{F} \) is the force, \( q \) the charge, \( \mathbf{v} \) the velocity, and \( \mathbf{B} \) the magnetic flux density. In most mass spectrometer designs, \( \mathbf{B} \perp \mathbf{v} \) and the ion travels along a circular path. The force provides the centripetal acceleration (Equation 13):

\[ F = qvB = \frac{mv^2}{r} \] (13)

Rearrangement gives Equation (14):

\[ mv = Bqr \] (14)

showing that magnetic fields discriminate particles according to their momenta.

Combining Equations (9) and (14) gives

\[ \frac{m}{q} = \frac{B^2r^2}{2V} \] (15)

which defines the radius of the path in the magnetic field for a given ion species. By taking the differential of each side of Equation (15), it can be shown that

\[ \frac{m}{\Delta m} = \frac{r}{2\Delta r} \] (16)

The quantity on the left-hand side of Equation (16) is known as the resolving power. The mass resolution depends on other factors including source and collector slit widths.

A monoenergetic ion beam focused at the entry of a uniform magnetic field is refocused after a deflection of 180°.\(^{(15)}\) Hence semicircular magnets formed the basis of a number of early isotope ratio mass spectrometers.\(^{(35,52)}\)

By the 1930s, theory was developed for focusing with magnetic sector fields\(^{(20)}\) and sector magnets gained favor because of their smaller size and hence lower costs.\(^{(17,18)}\)

By analogy many terms associated with light are used in ion optics. For normal incidence, the object focal point (source slit), image focal point (collector slit) and center of curvature lie on a straight line for a normal geometry sector magnetic field (Figure 10a). This is termed directional focusing. There is only one path where the ions are deflected 90° for the 90° sector magnetic field shown in Figure 10(a). Ions traveling with different momenta at larger and smaller radii are deflected less and more than 90°, respectively. They are nevertheless focused on a curved focal plane.

Theoretical treatment of the normal geometry case predicts good focusing for small angles of divergence, \( \alpha \). Terms containing \( \alpha^2 \), \( \alpha^3 \), etc. are neglected so the conditions are referred to as first-order focusing. Perfect focusing can be accomplished by appropriate curving of the pole pieces\(^{(53)}\) as shown in Figure 10(c). For the ion beams to cross the axis of symmetry \( AX \), Equation (17) holds:

\[ Y = x \frac{x_0 - x}{(r_m^2 - x^2)^{1/2}} \] (17)

As the curved shape is hard to manufacture, parts of the curve are approximated by circles or straight lines to achieve second-order focusing. For the latter, first- and second-order focusing requires (Equation 18),

\[ \tan \varepsilon = -\frac{1}{2} \tan \frac{\phi_m}{2} \] (18)
where $\varepsilon$ is the angle between the actual and normal incidence and $\phi_m$ is the magnetic field angle. The object distance $l$ from the source focal point to the magnetic field boundary is given by Equation (19):

$$l = \frac{2}{3} r_m \cot \frac{\phi_m}{2}$$

(19)

An example of this geometry used by Finnigan MAT and others is shown in Figure 10(b). Note that the center of curvature is no longer in the plane of the source and collector slits and the angle of deflection is not equal to the angle of the magnetic field. This is referred to as extended geometry. A bonus with this geometry is focusing in the axial direction termed $z$-focusing (compare Figures 10a and b).

A variety of shapes have been used in symmetrical and nonsymmetrical arrangements to achieve first- and second-order focusing. Slightly rounded pole pieces used on the Vacuum Generators’ PRISM generate a collector focal plane that is nearly normal to the central ion beam. In the asymmetric Europa Scientific 2020, heavier ions such as CO$_2^+$ are deflected through 120$^\circ$ and the image distance is shorter than the object distance. For hydrogen isotopes, mass 2, H$_2^+$ follows the same path but mass 3, HD$^+$, is deflected through a side arm at a smaller angle and its image distance is longer than the object distance. Another factor considered in designs is that the magnetic field extends slightly beyond the pole pieces. Inhomogeneous magnetic fields have also been used to achieve higher-order focusing.

When the magnetic field or source potential difference is slowly changed, ion currents are swept across the collector slit, generating peaks on a chart recorder or oscillographic display. For an ion beam of uniform cross-section, the ratio of the width of the flat topped peak to its base is $(C - S)/(C + S)$ where $C$ and $S$ are the widths of the collector slit and the thickness of the ion beam (~ source slit width), respectively (Figure 11). In practice, peaks are rounded on the tops and have tailing at the baseline. Factors contributing to these departures from the ideal case are the response time of the amplifier, imperfections in the slits, and the energy spread of the ion beam. A problem arises when an isotope is so low in abundance that it cannot be detected in the tail of the adjacent ion current. The term ‘abundance sensitivity’ is used to describe how well an instrument can detect a minor ion current. It is the ratio of the ion current at mass $M$ over its contribution at mass $M + 1$. For sector magnetic field instruments, abundance sensitivities approaching $10^5$ are achieved at mass 100. By using two consecutive MAs with a slit and ion acceleration after the first, the abundance sensitivity can be increased to $10^8$ (see section 2.6.4). The magnetic sector analyzer is said to be single focusing because it is direction focusing and requires a uniform energy ion beam. Directional focusing can also be realized in the radial electrostatic field that exists between concentric cylindrical condenser plates, i.e. electrostatic analyzer (ESA). It turns out that certain combinations of electrostatic and magnetic analyzers can be used whereby the velocity dispersion in one field is counterbalanced by that in another. Such geometry is required for sources with a wide energy spread (see Figure 16). A compact version with a mass of less than 5 kg has been built for space exploration applications.

2.6 Collector Design and Measurement of Ion Currents

Flat-top peaks (Figure 11) are desirable even if the mass spectrometer is not used in a scanning mode, as the ion current entering the collector will remain constant with small variations in the source potential difference and/or magnetic field. This requires that the collector slit be wider than the thickness of the ion beam. This reduces the instrument’s resolution $R$ which, for a symmetrical MA, is given by

$$R = \frac{\Delta m}{m} = \frac{S + C}{r_m}$$

(20)

Equation (20) neglects a term in the numerator dependent upon the beam’s divergence angle and applies to the condition of the bases of ideal peaks just touching. In practice, the inverse of $R$, the resolving power, is used. Thus, the minimal separation of peak of mass 100 from that of 101 is stated as a resolving power of 100. To account for tailing, resolution specifications are based on criteria for the valley between two comparable peaks, usually 5–10% of the peak height.

For many lighter elements, isotopic ion currents are in the range $10^{-9} – 10^{-12}$ A. For other elements, the minor ion current may be lower than $10^{-15}$ A. Different
measurement strategies are required to cover the range of currents.

2.6.1 Faraday Cup

A Faraday cup is usually a rectangular metal box with one open end into which the ion current enters (Figure 12). The box is connected electrically to the input of an amplifier with a very high impedance ($10^{15}$ Ω) input. The amplifier measures the electron current going to the box to neutralize incoming positive ions (or electron current leaving the box if negative ions are collected).

When ions hit surfaces of the box, some secondary electrons are emitted, giving an incorrect reading of the ion current. Secondary electron emission is suppressed by having deep boxes which may have inner walls coated with materials such as carbon. A repeller plate held at a potential of about $-45$ V with respect to ground, is also placed in front of the entrance to force secondary electrons to return to the box (Figure 12). Grounded metal guard plates or washers are placed between the repeller and the Faraday cup to prevent electrical leakage between them. Permanent magnets may also be used in the collector to prevent escape of secondary electrons.

Amplifiers operate with grid leak resistors of the order of $10^9$–$10^{11}$ Ω, a current gain of $\sim$10$^7$ and a voltage gain near unity. In earlier instruments, thermionic electrometer tubes were used.[17,18] They were subject to drift and, during the 1950s, commercial vibrating reed electrometers (Cary, USA; Vibron and Keithley, UK) were used because of their stability. In these devices, an input DC (direct current) potential is applied through a resistor to a capacitor with vibrating plates, thereby generating an AC (alternating current) signal proportional to the input. The AC signal is in turn amplified, converted back to DC and applied as negative feedback to cancel the input voltage (null method). The amount of negative feedback is measured. Today, relatively inexpensive integrated circuit amplifiers with MOSFET (metal oxide silicon field effect transistor) inputs have sufficiently high impedances and current stabilities of better than $10^{-15}$ A in typical operation.

Amplification as described above is based on Ohm’s law. Another approach is to charge a capacitor for a fixed time and measure the voltage across it (Equation 21):[57,58]

$$V = \frac{Q}{C} = \frac{I \, dt}{C}$$  \hspace{1cm} (21)

where $I$ is the current, $Q$ is the accumulated charge $\frac{I \, dt}{C}$ and $C$ is the capacitance.

2.6.2 Electron Multiplier

Emission of secondary electrons, which was undesirable for the Faraday cup detector, is the basis of operation of the electron multiplier.[35] Ions arriving at the collector slit are accelerated to more forcefully collide with the conversion dynode which emits secondary electrons (Figure 13). These are in turn accelerated to the next dynode to generate more secondary electrons. The dynodes are constructed of layered metals (Be on Cu, Mg on Ag). They are also curved to focus the electrons on subsequent dynodes in the chain. With as many as 14 stages, the current gain can be greater than $10^5$.

Compact versions of electron multipliers include the channel electron multiplier (CEM). This is a hollow tube with inner semiconducting surfaces. The secondary electrons possess transverse velocity components and strike the inner wall but they are also accelerated axially by a potential of $\sim 2$ kV applied to the ends of the tube.

Electron multipliers may be used for current amplification or for generating pulses from individual incident ions at low currents. For pulse counting, the Daly detector[59] has found favor. Initial attempts to use scintillators to convert impinging ions into light pulses for amplification by photomultiplier tubes failed because the ion bombardment damaged the scintillator. Therefore, secondary electrons rather than direct ion beams were directed to the scintillator. The Daly detector is more proficient in distinguishing ion counts from background signal (known as dark current). A Daly detector may be preceded by a modest electron multiplier and currents as low as $10^{-20}$ A have been measured by pulse counting. Higher currents
produce more losses because of counter dead time and a maximum (∼10⁻¹⁰ A) is reached whereby the detector does not respond with distinct pulses.

### 2.6.3 Scanning

For an element containing many isotopes, the tendency has been to scan the mass spectrum and record ion peaks (see Figure 11). Scanning by changing the source potential difference (high voltage (HV)) is fast but the energies for different isotopic ions also change. This mode permits the use of permanent magnets for cost savings and stability. Scanning the magnet current is slower because of hysteresis which can be improved by the use of laminated magnet construction. Tracing of entire peaks is not required once their shape is optimized. Jump-scanning can be used whereby ion currents are measured at a few points on the peak tops and on the baseline between peaks.

Scanning with measurement of one peak at a time incurs errors due to changes in ion production – while measuring peak B, previously measured peak A might be higher or lower than when it was recorded. Some sources have larger fluctuations in ion production than others. With more stable electronics and faster scan rates, the situation has improved. However, scanning is inefficient for data acquisition as other ion currents are ignored when one peak or baseline is being measured.

### 2.6.4 Simultaneous Ion Collection

Collection of two or more ion currents with constant electric and magnetic fields (simultaneous collection) was established early in the history of IRMS. Data collection approaches 100% efficiency and fluctuations in ion production increase or decrease all ion currents proportionally.

An assembly suitable for collecting two isotopic ion currents from either N₂⁺, CO₂⁺, SO⁺, or SO₂⁺ is shown in Figure 12. A minor ion current (heavier isotopic species for the above ions) passes through to the narrow deep Faraday cup while the major ion current plus perhaps another minor ion current is collected in the larger box.

A triple collector with a central narrow slit and two outer wide slits over three deep Faraday cups is frequently used with the above ions. It has the advantage that masses 44, 45, and 46 can be collected for CO₂⁺, providing carbon and oxygen isotope data simultaneously. The occurrence of ¹²C¹⁷O¹⁶O⁺ and ¹³C¹⁶O₂⁺ at mass 45 and other combinations at mass 46 necessitate corrections. Triple collection has been used with other elements, such as ⁷⁶SeF₅⁺, ⁸⁰SeF₅⁺, and ⁸²SeF₅⁺ (64) and even more collectors (multiple collectors (MCs)) are available in some instruments, e.g. 12 Faraday cups in the Nu plasma ICP (inductively coupled plasma)/IRMS (section 5). MCs are not limited to Faraday cups. Electron multipliers in the current amplification or pulse counting modes can be combined with each other or with Faraday cups. For gas source IRMS, the combination of dual inlet and simultaneous collection provides the parameters for the definition of δ-values (Equation 2).

One device used in multicollector systems for resolving very low ion currents buried in an adjacent peak tail, is the retarding potential quadrupole (RPQ) such as the RPQ II option on Finnigan MAT 262 instruments. The RPQ operates on the low-mass side of the major ion...
peak where the ions possess lower kinetic energy due to collisions in the ionization region and/or along the flight path. For Th isotopes, the major ion current, $^{232}\text{Th}^+$ is collected in a Faraday cup. However, some $^{233}\text{Th}^+$ ions arrive at the same position as that of $^{230}\text{Th}^+$ which is about $1.5 \times 10^5$ times less abundant. An RPQ is placed where the $^{230}\text{Th}$ ion current impinges and an energy threshold is set to stop the lower energy $^{230}\text{Th}^+$. The more energetic $^{230}\text{Th}^+$ ions pass through into an electron multiplier to be converted to pulses. Another approach used in the ISOLAB-54 is to have the minor beam filtered by an ESA placed after the multicollector.

2.6.5 Simultaneous Collection Electronics

Null methods were used in earlier measurements of simultaneously collected ion currents.$^{32,33,60}$ In the version shown in Figure 14, the output voltage of the major ion current electrometer amplifier is larger than that of the minor current amplifier (despite the latter’s larger feedback resistor). The output of the major current amplifier is placed across a decade put-and-take potentiometer. The put-and-take feature means that if a resistance, say 100 $\Omega$, is added above the central wiper, the same resistance is removed below the wiper so that the total resistance remains the same, typically 10 k$\Omega$. The total resistance between the ground and the central wiper is measured to four or five significant figures by reading numbers on dials for each decade. The voltage at the center tap is adjusted to match that of the full output of the minor ion current amplifier. The output of the major ion current amplifier is converted to pulses. Another approach used in the ISOLAB-54 is to have the minor beam filtered by an ESA placed after the multicollector.

![Figure 14](image)

**Figure 14** Circuitry for null method of determining the ratio of two isotopic ion currents.

There are inexpensive ways to obtain a number proportional to the ratio of ion currents. Whereas five digits are required if full amplifier outputs are used, the put-and-take potentiometer can be retained and a cheaper three-digit DVM used to measure departures from null conditions. Inexpensive components can also be used with the charged capacitor method.$^{66}$

Today, the outputs of simultaneous collection MOS-FET operational amplifier integrated circuits undergo V to F conversion followed by inputs to counters (or integrated circuit ADCs (analog to digital converters)) and interfacing to a computer. The computer calculates the ratios of ion currents and ultimately the $\delta$-values of samples.

2.7 Automation of Magnetic Sector Mass Spectrometers

Early IRMS was manually intensive with the operator continually adjusting filament currents on TIMS instruments, scanning and measuring peak heights. The DI/IRMS operator switched the inlet system, checked that reference and sample major ion currents were matched, and measured deflections on a chart recorder. Today, these operations are fully automated.

Through optical coupling to provide the necessary electrical insulation, the filament of a TIMS can be controlled through feedback from the major ion current amplifier. Magnetic fields are stabilized and measured by Hall probes.$^{67}$ Scanning constitutes selection of magnetic field values and even masses (rather than the former settings of magnet currents) and entering them into a computer.

In DI/IRMS, a value can be chosen for the major ion current. Through feedback from the collector or pressure measuring devices, stepper motor-driven bellows (see Figure 6) are periodically compressed or relaxed to maintain the selected current. The adjustments are rapid.
because the position of the bellows is known to the computer along with values for the actual ion current and the selected current. The software calculates the number of steps and the direction that the motor must move.

Rather than evaluate corrections for each sample, two or three reference gases can be analyzed as samples at various times during a DI/IRMS run. At the end of the run, measured values for the references can be compared to accepted values, thereby providing correction factors to apply to other samples.

Gas samples attached to a manifold can be automatically introduced into the bellows, pressures adjusted to give the selected major ion current, and pumped away after analyses. A number of sample preparation lines including isotopic equilibration of CO₂ or H₂ with H₂O⁶⁸ and generation of CO₂ from carbonates reacted with H₃PO₄⁶⁹ or combustion of organic matter can be attached to an IRMS and fully automated.

3 CONTINUOUS FLOW ISOTOPE RATIO MASS SPECTROMETRY

3.1 Basic Concept

The minimum sample size for traditional IRMS is equivalent to ~1 mg of the element of interest because of the gas pressure required to meet viscous flow conditions. Further, the analysis usually consumes less than 1% of the prepared sample, so that most of the prepared sample is wasted. The sample size requirement can be reduced to the microgram range using CF/IRMS, also called isotope ratio monitoring (IRM).

In this scheme, the prepared gas is swept through the mass spectrometer source with a carrier gas, usually He. Different ion currents corresponding to isotopic species are simultaneously collected, as with a traditional MC/IRMS. However, instead of measuring currents as such, they are integrated throughout the time that the sample is in the source. In other words, the total charge, Q, generated for each isotopic ion species is collected in each Faraday cup and measured. The He carrier ensures that viscous flow conditions are met.

An overview of a CF/IRMS system is shown in Figure 15(a). A prepared sample is flushed through a long quartz capillary to a split interface. The region between the two concentric cylinders of the interface is open to the ambient atmosphere. Therefore, it should be placed in a fume hood or other venting system for noxious gases. The interface is required because the total flow of gas into the ion source must be less than 0.5 mL min⁻¹ and the required flow through some preparation devices can be 10² times higher. Thus, sample is also wasted with

![Figure 15 Diagram of (a) CF/IRMS system and various preparation devices, (b) elemental analyser, (c) compound-specific analyzer, (d) chemical reactor, and (e) laser probe.](image-url)
CF/IRMS but, despite the loss, the minimum required mass of the element of interest is reduced by a factor of at least 10² compared to DI/IRMS. The split gas passes through another long quartz capillary (MS sniffer) into the mass spectrometer.

Nonlinearity of the mass spectrometer poses problems for CF/IRMS because the ion currents are transient. The shape of the I versus t plot for the processed sample is approximately Gaussian, whereas injected reference gases produce a nearly rectangular peak. If possible, peaks with the same area should be generated for all samples and the reference gas. One approach is to analyze a sample gas first and use the area of its major peak with electronic–mechanical feedback to adjust the volume of reference gas subsequently injected.

Clearly the benefits of CF/IRMS are small sample size requirements, high throughput, simplified preparative chemistry, the ability to measure the amount of prepared gas, and lower analytical costs. Precision is not as good as with DI/IRMS, but more than adequate for most applications.

A number of preparation devices have been attached to CF/IRMS instruments. Some have been fully automated, whereas others have been operated manually. These devices have also been used in DI/IRMS with cryogenic trapping of prepared gas and larger raw sample size.

### 3.2 Bulk Sample Isotope Analysis

The most frequently used preparation device with CF/IRMS is a combustion system such as in an elemental analyzer (EA), CNS analyzer, or automatic nitrogen, sulfur, and carbon analyzer (ANSCA). Although some are built in-house, commercial units such as Carlo Erba have carousel (autosampler) features for loading 50 or more raw samples. The procedure is termed bulk sample isotope analysis (BSIA) or bulk composition IRM. Submilligram quantities of the sample weighed into small tin cups (~3 mm diameter by 5 mm deep), are dropped into a vertical combustion tube (Figure 15b). Simultaneously, a pulse of O₂ is admitted into the He stream. The furnace is maintained at ~1100°C, whereas the exothermic reaction of oxidation of tin should realize a much higher temperature (~1600°C). Addition of solid oxidants to the cup is discouraged because the increased mass means increased heat capacity and probably a lower average reaction temperature. However, oxidants such as CuO, Cr₂O₃, and Co₃O₄ are placed in the bottom of the combustion tubes, sometimes as coatings on chemically inert spheres to avoid impeding gas flow. The combustion furnace is followed by a reduction furnace with Cu shavings at 600°C to reduce nitrogen oxides to N₂ and remove surplus O₂. Sometimes oxidation and reduction zones are included in one tube. A packed gas chromatography (GC) column separates the products of combustion. N₂, CO₂, H₂O, and SO₂. SO₂ and H₂O are often chemically removed, as C and/or N isotopes are measured in most applications. However, analyses of SO₂ (S isotopes) and H₂O (H isotopes) have also been carried out. With the latter, there is the problem of resolving HD²⁺ from HD⁺ and tailing of the HD⁺ peak which is ~10⁶ times higher. Possible solutions include high resolution of the peaks at mass three, use of an RPQ, or use of another carrier gas. As the He flow in BSIA is ~100 mL min⁻¹, a high split ratio is required of about 1:200.

For routine S isotope measurements on pure sulfide and sulfate minerals, it can prove expedient to remove the GC as SO₂ tends to stick to walls in vacuum systems. The reduction furnace should be retained to reduce any product SO₃ to SO₂.

Bulk δ¹⁸O analyses have been attempted with some success by adapting an EA for pyrolysis of organic materials, and inorganic compounds including carbonates, sulfates, and H₂O. One problem is co-generation of CO₂ and CO and production of the latter is encouraged by reaction at high temperatures (~1300°C) in a carbon-rich environment. Quartz combustion tubes should not be used because they exchange O isotopes with CO at high temperatures.

### 3.3 Multielement Isotope Analysis

The split interface in Figure 15(a) was dubbed a conflu interface by Finnigan MAT. In the standard conflu, a piston-driven capillary with He flow can be inserted additional to the sample inlet and MS sniffer capillaries. During measurements on N₂ and CO₂ prepared from the same sample with an EA, the CO₂ can be diluted by He permitting the same amplifier gains as for N₂ and avoiding overpressure in the source. In the triple conflu version, two more piston-driven capillaries are added for insertion of N₂ and CO₂ isotopic references. The sequence of analysis is:

1. With the source HV set for N₂⁺, momentarily insert and withdraw the N₂ reference capillary and measure Q₂⁹/Q₂⁸.
2. Q₂⁹/Q₂⁸ is measured for N₂ from the EA.
3. The source HV is adjusted for CO₂⁺ and the He dilution capillary inserted.
4. Q₄⁵/Q₄⁴ and Q₄⁶/Q₄⁴ are measured for CO₂ from the EA.
5. The He dilution capillary is withdrawn (optional). The CO₂ reference capillary is momentarily inserted and withdrawn for Q₄⁵/Q₄⁴ and Q₄⁶/Q₄⁴ measurement.
In addition to inserting the reference gas capillaries for each sample analyzed, raw material references can be randomly loaded into the autosampler.

The above system can be expanded to include SO₂. However, when the typical isothermal GC in an EA is adjusted to adequately separate N₂ and CO₂, the SO₂ emerges much later. Hence researchers tend to carry out δ³⁴S measurements separately with a shorter GC column to save time.

### 3.4 Compound-specific Isotope Analysis

In compound-specific isotope analysis (CSIA), a specimen is separated into different chemical compounds and suitable gases prepared from the separates for isotopic analyses,(73,74–76) Light HC (hydrocarbon) gases may be separated on a packed column GC. Heavier organic molecules require capillary GC techniques, although high-precision liquid chromatography has also been used.(85) The latter requires special transport of separated compounds into a combustion furnace by a moving Ni wire. The He carrier gas is introduced at the entrance to the furnace. A GC set-up for CSIA is shown in Figure 15(c). The separated compounds pass through a combustion furnace producing CO₂ and N₂, followed by a reduction furnace for converting nitrogen oxides to N₂. To minimize broadening of the peak of prepared gas reaching the IRMS, the furnace tubes have a small internal diameter (~1 mm). Thin wires of Pt, Ni, and Cu are inserted in the combustion tube and oxidized to give NiO and CuO which in turn oxidize the separated compounds. Water is removed by immersing a trap in a dry ice bath with a risk of plugging the capillary or by a Nafton⁶ hydroscopic capillary section. If N isotope measurements are conducted, the CO₂ is frozen out in a liquid N₂ trap.

Introduction of reference gases at the interface is more complex. It can be done before and after the chromatographic trace and perhaps when there is sufficient time, between successive GC peaks. However, as the amounts of sample vary with the specific compound, injection of different amounts of the reference is desirable to correct for nonlinearity in the IRMS. Satisfactory calibration may require diverting gas prepared from some specific compounds in order to insert the reference gas. An alternative is to apply known additions of standard mixtures to the raw sample.

Another problem is the isotopic fractionation in a GC column. For example, ¹³C-containing species elute sooner than ¹²C-containing species. With light gases, the separation is sufficient that there is time to collect all isotopic charges for a given compound. With heavier molecules, overlapping of peak tails requires monitoring of the changing isotopic ion current ratios and curve fitting.(86) (This is the origin of the term ‘isotopic ratio monitoring’.)

For determination of δ¹³C and δ¹⁵N values of trace atmospheric gases (CO₂, N₂O, CH₄, etc.), preconcentration steps are required prior to GC separation.(87) About 100 mL of air is needed for firm analyses of these gases, whereas 100 L would be required to process them for DI/IRMS.

### 3.5 Chemical Reactors

This category includes many possibilities whereby a suitable gas for isotopic analyses is prepared. It could constitute a manifold of many reactors where H₂ and CO₂ are isotopically equilibrated with H₂O for δD and δ¹⁸O determinations. Mixed-carbonate minerals may be treated with H₃PO₄ to release CO₂ sequentially from calcite, dolomite, and siderite in about 1 h, 2 days, and 2 months, respectively at room temperature. By monitoring the isotopic composition of the CO₂ evolved, the isotopic composition of individual minerals and their percentage occurrence in the sample can be ascertained. By increasing the temperature during the run, the analytical time is shortened. Individual reactors (Figure 15d) have been used to study carbon KIE during decarboxylation reactions and sulfur KIE associated with SO₂ evolution when SO₂Cl₂ is used as a chlorination agent. In principle, quite small microbiological and chemical reactors can be used to provide detailed measurements of isotope effects associated with HC oxidation, methanogenesis, denitrification, and other processes.

### 3.6 Laser Probe

Laser beams have been used for decrepitation of crystals to release gases(88) or as a heat source to promote chemical conversions over a limited area (down to ~10 μm diameters) on a solid surface.(89–102) They have also been used with powdered reactant mixtures for routine sample preparation. Whereas many units are stand alone or attached to DI/IRMS systems, their use with CF/IRMS is growing.(101,102)

For some materials, laser beam energy is not absorbed effectively at the target spot. The material may be highly reflective, highly transparent, easily fractured, or conduct heat away from the spot too quickly. In the case of the latter, yields of gases are higher at the edges than near the centre of the specimen’s surface. In the former, the solid angle for heat conduction is π steradians, but 2π steradians for the latter. The choice of wavelength also influences the yields. The Nd : YAG laser operates in the infrared at 1.06 μm and has proved particularly suited to the production of SO₂ from certain sulfide minerals (PbS, ZnS, FeS, FeCuS₂, Ag₂S, Sb₂S₃). Its frequency can be doubled or quadrupled (ultraviolet) for other
applications. A CO₂ laser (10.6 μm) has a frequency which closely matches a fundamental vibrational mode in CO₃²⁻ and hence the energy absorption should be similar among different carbonate minerals.

Isotope fractionation during laser-assisted sample preparation can be substantial. Mineral dependent shifts in δ²⁴S values (as much as 5‰ lower) during SO₂ preparation result during evaporation, condensation of unreacted vapor, and chemical oxidation.⁹⁵,⁹⁶

A laser probe attachment suitable for preparation of SO₂ from sulfide minerals is shown in Figure 15(e). The mirror that reflects the Nd: YAG laser beam (≈10⁷ W m⁻²) towards the sample is transparent to visible light. Hence the specimen is viewed with a video camera connected to a TV monitor with an option of up to 500 x magnification of the surface relief by a contour synthesizer. Injections of O₂ is coincident with the laser beam pulses (~1 s duration). A dust filter should be placed at the exit of the chamber to avoid plugging the capillary. Excess O₂ can be consumed with a furnace containing Cu or the sample can be purified by passage through a GC column.

Material (ZnSe, BaF₂) for the window above the reaction chamber is chosen on the bases of transmission efficiency at the wavelength of the laser beam and its resistance to chemical attack. BaF₂ is desirable during fluorination of silicates to release O₂ for preparation of SF₆ for δ³⁴S determinations.⁹⁷,⁹⁸

The sample holder sits on a stage which can be moved in the x and y (and even z) directions either manually or by computer controlled stepper motors.

A CF/IRMS CO₂ laser attachment has been recently developed to volatilize carbonaceous materials with the evolved gases subsequently combusted to produce CO₂ for δ¹³C measurements.¹⁰⁰

### 4 SECONDARY ION MASS SPECTROMETERS

In secondary ion mass spectrometry (SIMS), secondary ions are produced at the surface of a sample bombarded with focused primary ions (O²⁺, O⁻, N²⁺, or Ar⁺ from a duoplasmatron;¹⁰³ Cs⁺ or Rb⁺ by TIMS; or Ga⁺ or In⁺ from a liquid metal field emission source). Samples are cast into a thick (~5 mm) epoxy disk. One surface of the disk is ground and polished flat to expose the sample. A thin gold coating is then applied by vapor deposition to prevent static charge build-up during bombardment by the primary ion beam.

Initially, secondary ions were analyzed by quadrupole mass analysis (QMA) or time-of-flight (TOF) mass spectrometry (MS) (section 7). A few isotope ratio measurements of heavier elements have been made with these ion probes but it became clear that double focusing mass spectrometer optics were required to provide sufficient resolution (Figure 16). Multicollection of ions is also possible with the latter. Ion currents are measured with electron multipliers usually in the counting mode. Commercial instruments include the ISOLAB-54, Cameca IMS-1270, and SHRIMP (sensitive high-resolution ion microprobe) developed at the Australia National University.¹⁰⁴–¹⁰⁶ These instruments have emphasized in situ U/Pb dating of zircons and have found more than one event in a crystal. However, they have also been used with lighter elements.¹⁰⁵,¹⁰⁶ One problem with SIMS is the matrix-dependent large shifting of δ-values (up to 100‰ for light elements). Reproducibility of the order of a few ‰ can be obtained by alternately bombarding the sample and a number of standards containing minerals that occur in the sample. Positive features of SIMS are high resolution analyses of surfaces and, to some extent, measurements of variations in composition and isotope abundances with depth. The primary beam can also be electrostatically deflected to conveniently scan the sample’s surface.

### 5 INDUCTIVELY COUPLED PLASMA MASS SPECTROMETERS

As with SIMS, inductively coupled plasma mass spectrometry (ICP/MS) was initially used for chemical analyses and was quadrupole mass spectrometry (QMS) and TOF/MS based. Commercial units including the Perkin-Elmer Elan 5000, Hewlett-Packard HP4500, and Spectromass 2000 have been examined for performance in isotope ratio measurements.¹⁰⁷ Although acceptable for many investigations, such instruments do not produce flat-topped peaks and cannot be used for multiple collection. Precise IRMS required incorporation of MC double
focusing mass spectrometers. Commercial units include the VG Plasma 54 with nine Faraday collectors and one secondary electron multiplier (SEM), and Nu Instruments Plasma with 12 Faraday cups and three SEMs.

The ICP source contains a plasma torch and conical extraction plates (Figure 17). The torch has an outer SiO2 tube 18 mm outer diameter and 100 mm long. A coil of three turns of water-cooled Cu tubing around one end of this tube is connected to a radiofrequency generator (~1 kW, 27.12 MHz). Two inner concentric SiO2 tubes are ring-sealed to the outer tube at the end opposite to the coil (not shown). The innermost tube ends with a 1.5 mm capillary just short of the coil (shown) to introduce the sample to the plasma region. Argon, introduced through side arms (not shown), cools the inner wall of the outer tube (>10 L min⁻¹) and serves as a carrier (~1 L min⁻¹) for the sample. The sample and carrier gas are exited by a Tesla coil and an intense plasma (8000 K) is generated with energy supplied by the radiofrequency coil. Samples can be introduced into the plasma by nebulization, vaporization, and laser ablation. Only small particles and droplets (<4 μm diameter) are conveyed by the carrier gas into the plasma region. Under plasma conditions, most ions are atomic. They are extracted by a water-cooled nickle cone (sampler) with an orifice of ~1 mm diameter pointed at the plasma region (Figure 17). A more pointed skimmer cone lies beyond the sampler. The space between the cones is pumped to remove the large flux of gas which passed through the sampler, thereby serving as an intermediate stage in reducing the pressure from ~1 atm in the plasma region down to high-vacuum conditions suitable for the analyzer region. A quadrupole lens system can be used to change the cross-section of the extracted ion beam from a circular to narrow rectangular shape suitable for slits of a double-focusing mass spectrometer. Another quadrupole lens system after the ESA and MA can be used to alter the dispersion of the ion beams so that they enter consecutive Faraday cups in the mass range chosen for measurement.

The ICP/IRMS technique has some inherent problems. Although the bulk of the ions are atomic, amounts of some molecular ions generated from the atmosphere and carrier gas are sufficient to cause interference. Thus O₂⁺ is isobaric with 32S⁺, 40Ar⁺ with 80Se⁺, etc. From the viewpoint of absolute isotope ratio abundances, mass discrimination in ICP/IRMS can be very large, e.g. ~4% per mass unit with Se. Mass discrimination as qualitatively illustrated in Figure 17 is attributed to at least two mechanisms. One is space charge effects, whereby positive ions leaving the skimmer undergo mutual repulsion which deflects lighter ions preferentially. The second mechanism is nozzle separation, occurring in the supersonic gas jet in the region between the plasma torch and the skimmer. Both processes favor the heavier isotopes in the central transmitted beam. Fortunately, MC/ICP/MS has the capability of addressing some of its own problems. The mass discrimination can be evaluated using isotopic reference materials or by also collecting ion currents from elements which do not display significant natural isotopic fractionation. Thus by collecting ions from 203Tl and 205Tl, together with 204Pb, 205Pb, 206Pb, and 208Pb, mass-bias corrections can be made to the measured Pb-isotope abundances. Isobaric interference corrections can also be made; e.g. contribution of 204Hg to the 204Pb peak can be calculated if 202Hg is also collected.

The ICP/IRMS technique is clearly an emerging tool with many problems that are being aggressively addressed. Attractive features are the ability to work with impure solutions with concentrations of the element of interest <1 ppm. Analysis time is a few minutes with ~1 µg of sample consumed. Isotopic reference solutions can be injected by20 creating a mimic DI/IRMS.

6 ACCELERATOR MASS SPECTROMETERS

Accelerator mass spectrometry (AMS) uses accelerators (tandem, cyclotron, linear) in many modes to accomplish the measurements of abundances of very rare isotopes (below 10⁻¹² percent). Despite the size of these instruments and high capital/operating costs, there are at least 28 AMS laboratories worldwide. The scheme was first used in a cyclotron to measure ³He. The analytical objective is removal of interfering masses (isobars) during charge-changing collisions at energies of a few MeV. In some cases the negative ions of interfering isotopes are not stable; examples are ¹⁴N, ²⁸Mg, ³⁶Ar, and ¹²⁹Xe during ¹³C, ²⁸Al, ³⁸Cl, and ¹²⁹I analysis, respectively. In other situations, various approaches such as energy loss rate are used for removal of undesirable isobars.
In practice, a number of geometries have been devised to deal with specific problems. Combinations of electric and magnetic fields are placed between the source and accelerator. A frequently used source is a Cs gun, which directs primary ions onto a solid surface. Initially, neutral species are sputtered, but soon build-up of Cs on the surfaces lowers the work function and promotes release of negative ions (section 2.4.1) in microamp quantities. The ions are moderately accelerated and pass through ESA and MAs to the accelerator. There the ions are accelerated to several MeV energy and lose electrons by passing through a foil or colliding with a gas. Molecular ions decompose, and atomic ions emerge with charges of +3 or higher. After the accelerator, combinations of ESA and MA fields ensure that remaining unwanted ions do not reach the detector.

The AMS method has been used mainly for $^{14}$C dating of old materials, the sample size (<1 mg) being much smaller than that required for radioactive counting (<1 g). In this application, tandem accelerators with voltages around ~1.5 MV can be used (low-energy AMS). With heavier isobaric pairs, higher-voltage accelerators are required (high-energy AMS). A crucial aspect is that the cross-section for small-angle scattering of ions of residual gas decreases dramatically with increasing ion energy. Operation in the MeV range increases the abundance sensitivity by several orders of magnitude over that realized in the keV range employed with conventional tandem analyzers.

7 OTHER ISOTOPE RATIO MASS SPECTROMETERS

Numerous other mass spectrometer designs have been used for IRMS, of which a few will be described briefly. Some have unique characteristics which makes them ideal for specific tasks. Most have limitations that are overcome by MC/IRMS.

QMS can operate with a variety of sources for IRMS\(^{114}\) (sections 4 and 5). Ions are directed along the axis of four symmetrically placed parallel cylindrical metallic rods (approximating hyperbolic surfaces). Through combinations of radiofrequency and DC voltages applied to opposing rods, ions oscillate at right angles to the axis with trajectories described by the Mathieu equation.\(^{20}\) Scanning can be done by changing either the radiofrequency or DC voltages to permit transmission of certain ions. Advantages of the instrument are: small size, rapid scanning, resolving power up to ~8000, electric control of the resolving power, and linear operation up to pressures ~10\(^{-4}\) torr, which in turn embraces a large dynamic range of ion currents.

A TIMS/QMA device, known as the thermal ionization quadrupole (THQ) offered by Finnigan MAT, combines the MAT 261 source with a Balzers quadrupole mass analyzer (Type QMA 150) and has a mass range of 500 amu. Its performance with negative ions of B, Cl, Br, and I has been compared to magnetic sector IRMS data.\(^{115}\) The precision for the latter on average was about three times better than for the former for isotope ratio and IDMS measurements.

Gas-source QMS set-ups, such as the Balzers GAM 500, have been used for rare gases, metallic gases such as UF\(_6\), and even coupled to an EA for $^{13}$C and $^{15}$N measurements.\(^{114}\)

Another interesting IRMS device is the omegatron developed in the late 1940s.\(^{116}\) It operates on the cyclotron principle. Ions are formed along an electron beam (~1 μA) that is parallel to a magnetic field and axial to two parallel nonmagnetic plates. When a radiofrequency voltage is applied to the plates, ions which are consistent with the cyclotron frequency (Equation 22),

$$f = \frac{Bq}{2\pi M}$$

follow an outward spiral path of a few thousand revolutions to arrive at a collector.

The analyzer region can be quite small and a useful instrument can be constructed with a permanent magnet. However, the dependence of the resolution on $B^2$ has promoted the use of large magnets. Another interesting property is the dependence of resolution on the inverse of the mass of the ion.

One problem with the omegatron is collisions over the long ion path, leading to reduction of ion currents. Traces of hydrogen in the system promote hydride ion species. H\(_3^+\)/HD\(^+\) ratios of 2 have been observed\(^{117}\) compared to <0.1 in typical EI sources. KrH\(^+\) species have been found to comprise as much as 40% of the Kr\(^+\) spectrum.\(^{117}\) Consequently, the omegatron has been seldom used for IRMS analyses of gases, although it has some unique desirable features.

There are applications which require very high resolution at low masses, such as interference of H ions during $^4$He/$^3$He analyses. The necessary resolution for separating H\(_3^+\) and HD\(^+\) is ~2000 and for HD\(^+\) and $^3$He\(^+\), ~700. The latter was realized with a QMS device\(^{114}\) and omegatrons\(^{117,118}\) and the former with an omegatron.\(^{117}\)

TOF MS has been applied to IRMS, notably with SIMS sources. Such an instrument can be a drift tube of length $L$.\(^{119}\) At one end, short bursts of ions are generated and travel down the tube. A given ion species arrives at the
collector, at time $t$ later given by Equation (23): 

$$ t = \frac{Lm^{1/2}}{(2Vq)^{1/2}} $$

(23)

where $V$ is the source HV. Gating of the pulse and the collector are accomplished by means such as electrostatic grids to avoid interrupting the ionization and collector electronics.

One disadvantage of the above mass spectrometers for IRMS, the inability to carry out MC, is being addressed by increasingly more sensitive detectors and faster scanning.

Another mass spectrometer for which MC is possible is the cycloidal mass spectrometer. It is based on the fact that a uniform magnetic field crossed with a uniform electric field possesses perfect double focusing in a plane normal to the magnetic field. If an ion leaving the source entered only a magnetic field, the path would be a circle. However, if it travels initially against an applied electric field, its velocity component in that direction is reduced to zero and then increased in the opposite direction. The radius of the path increases with increasing speed and the path is a cycloid. Problems with the instrument include space charge build-up and difficulty in constructing a uniform electric field. However, these have been addressed to build a reliable MC isotope ratio mass spectrometer for H isotopes.

8 APPLICATIONS

8.1 Introduction

IRMS has been developed for all relevant elements. Although initially in the domain of the physical scientists, because of their ability to develop the instrumentation, IRMS practitioners were joined by earth scientists as commercial instruments became available. The ranks have been gradually augmented by archaeologists, biologists, space scientists, forensic scientists, and industrial and medical researchers. Consequently the collective published articles on IRMS applications number in the tens of thousands and only a few examples will be mentioned.

Multi-element IRMS has been particularly revealing in certain applications. The isotope fractionation of some elements is dominated by one or two mechanisms. Variability in H/D and $^{18}O/^{16}O$ ratios is due mainly to differences in the vapor pressures of isotopic species of water. The KIE in bacterial reduction is responsible for large variations in $^{34}S/^{32}S$ and $^{15}N/^{14}N$ ratios. Isotopic selectivity during photosynthesis is a major factor in altering $^{13}C/^{12}C$ ratios, although the lower flux of bacterial generation of methane is accompanied by much larger KIEs. The spread in natural $^{11}B/^{10}B$ ratios is the result of isotopic exchange between boric acid and borate ion in aqueous solutions. For other elements such as Ar and Pb, isotopic abundance variability is due to their radiogenic isotopes (isotopes produced by radioactive transformations).

For mass-dependent fractionation, a relationship exists between $\delta$-values and the masses of the isotopes of a given element (Equation 24):

$$ \frac{\delta_3}{\delta_2} = \frac{m_3 - m_1}{m_2 - m_1} $$

(24)

where ‘2’ and ‘3’ are two heavier isotopes whose $\delta$-values are referred to the lighter isotope ‘1’. It is desirable to measure as many isotope ratios as feasible as departures from this relationship identify mass-independent processes such as radiogenic isotope production and/or contamination in prepared samples.84 This concept is also used to correct $T$ and $^{14}C$ data for mass-dependent isotope fractionation.

Applications can be grouped under four general categories: concentration measurements by isotope dilution, radioactive decay and nuclear reactions, isotope tracing, and isotope fractionation. These are not totally independent. The effectiveness of an isotopic tracer can be compromised if it is subjected to extensive isotopic fractionation. A suitable natural tracer may be generated by isotopic fractionation.

8.2 Concentration Measurements

Isotope dilution analysis (section 2.4.3) has been widely used to measure low concentrations of elements in a variety of materials including Cd in polyethylene, $^{122}$S in steel, $^{85}$Kr in the atmosphere, and I in food. In round-robin studies involving several methods, IDMS results have proved the most consistent, regardless of the IRMS instrumentation, and closest to certified values. An intriguing application in zoology is the measurement of total body water (TBW). If known additions of $D_2O$ and $H_2^{18}O$ are given to a subject (doubly labeled water (DLW) technique), it is possible to measure their energy expenditure. This technique has been applied to creatures ranging from humming birds to astronauts.

8.3 Radioactive Decay and Nuclear Reactions

Whereas radioactive counting techniques are better for measuring the half-lives of very rapidly decaying nuclides, IRMS has proved competitive over a wide range of lifetimes. Measurements can be made with either the parent or daughter isotope. For short half-lives (such as $^{85}Kr \sim 10$ years), measurements are made with the parent, whereas measurements of the daughter, often by ID, are used for long lived nuclei (e.g. $^{87}Rb \sim 4.5 \times 10^{10}$ years).
Radioactive decay is the basis for a number of age-dating methods (geochronology) for our earth and meteorites.\(^{129 \text{-} 132}\) Geochronological isotope clocks include \(^{238}\text{U} \rightarrow ^{206}\text{Pb}, ~^{235}\text{U} \rightarrow ^{207}\text{Pb}, ~^{232}\text{Th} \rightarrow ^{208}\text{Pb}, ~^{87}\text{Rb} \rightarrow ^{85}\text{Sr}, ~^{40}\text{K} \rightarrow ^{40}\text{Ar}, ~^{167}\text{Re} \rightarrow ^{167}\text{Os}, ~^{147}\text{Sm} \rightarrow ^{143}\text{Nd}, ~\text{T} \rightarrow ^{3}\text{He}, \text{ and } ^{14}\text{C} \rightarrow ^{14}\text{N}.\) Measurements of the latter (5730 years) is based on the isotopic composition of the parent by AMS (section 6). Perhaps the most famous study was \(^{14}\text{C} dating of threads from the Turin shroud.\) For \(T\) decay (12.26 years), IDMS measurements can be made on accumulated \(^{3}\text{He}\) in closed bottles over several months.

At nuclear reactor installations, IRMS is employed to monitor fuel burn-up with \(^{235}\text{U}/^{238}\text{U}\) ratios\(^ {146}\) and IDMS measurements of Gd isotopes\(^ {133}\) and to determine consumption of control rods \(^ {^{10}\text{B}^{11}\text{B}, ^{115}\text{Cd}^{114}\text{Cd}},\) neutron absorption cross-sections, and neutron flux. The IRMS of isotopes of many elements including \(\text{H}, \text{Li}, \text{He}, \text{Sr}, \text{U}, \text{and Pu}\) has been used in phases of development of nuclear weapons and global monitoring of their testing. The technique has also been used extensively to study the Oklo natural reactor in Gabon, West Africa\(^ {134 \text{-} 135}\).

### 8.4 Isotopic Tracers

Isotopic tracer or label applications include planned additions of artificially or naturally enriched isotopes and scenarios where tracers enter a system naturally or by inadvertent industrial additions.

The most widely used artificially enriched isotope tracer is \(^{15}\text{N}\) in studies of plant nutrition, soil N transformation, N fixation by plants and bacteria, and animal health.\(^ {136 \text{-} 137}\) A recent medical breakthrough in routine use is the noninvasive detection of \(\text{Helio bacter pylori,}\) a bacterium that causes ulcers. It can be detected by having the subject consume \(^{13}\text{C}\)-labeled urea which the organism converts to \(\text{NH}_3\) and \(\text{CO}_2\). Marked increase in \(^{13}\text{C}\) values is evidence of the bacterial conversion.

An example of using the spread in natural isotope abundances for isotope labeling was the use of \(\text{SO}_4^{2-}\) with high \(^{34}\text{S}\) and \(^{18}\text{O}\) values in artificial rain to study S conversions in soil cores with initially lower \(\delta\)-values.\(^ {138}\) The sour \(\text{H}_2\text{S}-\text{rich}\) gas industry often emits \(\text{SO}_2\) with \(^{34}\text{S}\) values much higher than those of pre-industrial environmental acceptors. This constitutes a large-scale tracer experiment for studying the fate of atmospheric S in surface and groundwater, soil, plants, and animals.\(^ {139}\) A similar example of industrial labeling of emissions is the \(\text{Sr}\) isotope composition of fly-ash from coal-fired power plants.

During terrestrial growth, carbon isotopes in plants are fractionated to different extents by three photosynthetic mechanisms; \(\text{C}_3\) or Calvin–Benson (\(\delta^{13}\text{C} \sim -35 \text{ to } -31\%\)), \(\text{C}_4\) or Hatch–Slack (\(\delta^{13}\text{C} \sim -14 \text{ to } -10\%\)), and crassulacean acid metabolism (CAM; \(\delta^{13}\text{C} \sim -20 \text{ to } -10\%\)).\(^ {140 \text{-} 142}\) As the shifts in \(\delta^{13}\text{C}\) values are relatively small in food chains,\(^ {140 \text{-} 142}\) photosynthetic C-isotope fractionation has produced natural tracers for many uses. With \(\delta^{13}\text{C}\) values from bone collagen, archaeologists can ascertain the onset of maize (\(\text{C}_4\)) cultivation in a society that previously hunted animals in a \(\text{C}_3\) environment. Adulteration of maple syrup (\(\text{C}_3\)) or apple juice (\(\text{C}_3\)) with corn syrup (\(\text{C}_4\)) or cane sugar (\(\text{C}_4\)) has been detected by \(\delta^{13}\text{C}\) values and the evidence used by government prosecutors in court trials.

The isotopes of \(\text{C}, \text{N}, \text{and S}\) have distinct ranges of \(\delta\)-values for marine and continental environments.\(^ {143}\) This provides estimates of fluxes of organic matter from both environments into estuarine food webs\(^ {144}\) and insights into interesting topics such as the migration of whales.\(^ {145}\)

The difference in \(\delta^{13}\text{C}\) values for synthetic and natural compounds has been used for detecting food adulteration and the presence of performance-enhancing drugs such as testosterone in athletes, horses, and greyhounds. Changes in the \(\delta^{13}\text{C}\) of atmospheric \(\text{CO}_2\) recorded in situ and in proxy records such as tree rings and trapped \(\text{CO}_2\) in glacier cores have been linked to increasing atmospheric \(\text{CO}_2\) content and the increasing combustion of fossil fuels,\(^ {146}\) most of which have been ultimately derived from \(\text{C}_3\) photosynthesis.

### 8.5 Isotopic Fractionation

Applications based on isotope fractionation per se span a wide range of disciplines. Laboratory studies of isotope fractionation are directed towards the understanding of processes and developing methods of isotope separation.

Solid state diffusion mechanisms can be identified on the basis of the isotopic dependence of the diffusion coefficients.\(^ {48}\) Molecular flow diffusion of \(\text{UF}_6\) has been used for enriching isotopes of \(\text{U}\). Electrolysis of water leaves the residual solution more enriched in \(\text{D}\) and \(\text{T}\). Measurements of the fractionation has led to optimization for production of heavy water (\(\text{D}_2\text{O}\)). The process is also used to enrich \(\text{T}\) for radioactive counting.

Measurements of the equilibrium constants for isotope exchange reactions\(^ {147}\) are used to design isotopic enrichment schemes. The temperature dependence of the equilibrium constants is used for a variety of geothermometers.\(^ {148 \text{-} 150}\)

Measurement of the KIE during laboratory chemical\(^ {64 \text{-} 151 \text{-} 153}\) and microbial\(^ {152 \text{-} 155}\) conversions provides information about reaction kinetics and means of interpreting natural isotope fractionation.

The world’s meteorology system is a complex distillation apparatus for isotopic species of \(\text{H}_2\text{O}\) because of
their differences in vapor pressures. Isotope data for precipitation at many stations in the Northern Hemisphere fall along the global meteoric water line (GMWL).\textsuperscript{(156,157)}

The averages and variability of the $\delta$-values depend upon location and are determined by factors such as latitude, temperature, topography, and storm path. For H$_2$O that has undergone substantial evaporation, the slope for Equation (25) decreases to $\sim$5 and the intercept varies with location:

$$\delta D = \delta^{18}O + 11\%$$  \hspace{1cm} (25)

The $\delta D$ and/or $\delta^{18}O$ value of H$_2$O has been the basis of research topics in many disciplines including rate of lateral mixing of rivers\textsuperscript{(158)} and stratified lakes\textsuperscript{(159)} climatic records in ice\textsuperscript{(160)} and tree rings\textsuperscript{(161)} meteoric water intrusion into gas and oil reservoirs\textsuperscript{(162)} and turnover of body H$_2$O in animals\textsuperscript{(163)}

The $\delta^{18}O$ value of H$_2$O may be shifted substantially through exchange with carbonate and silicate minerals. Such water–rock interactions and associated microbial conversions have led to the extensive field of isotope hydrology or isotope hydrogeology. In this field, IRMS elucidates the origins of H$_2$O and ions, flow paths, mixing, chemical/biological processes, and changes in the ocean over geological time\textsuperscript{(159,164–171)}.

The IRMS technique has been used extensively to study topics in mineral and ore deposition including origin of metals and anions (e.g. S$^{2-}$), biological and chemical processes, thermometry, and chronology. Investigations have covered ore deposition temperatures ranging from below 100°C with considerable bacterial involvement\textsuperscript{(172)} up to magmatic conditions where minerals such as diamonds form\textsuperscript{(173,174)}.

Investigations of fossil fuel deposits using IRMS have addressed many questions concerning origin of CH$_4$\textsuperscript{(175–178)} gas–oil–rock correlations\textsuperscript{(177)} reservoir connections\textsuperscript{(175)} H$_2$S in gas\textsuperscript{(179,180)} S in coal\textsuperscript{(181,182)} in situ biodegradation\textsuperscript{(162)} and chemical reactions occurring during recovery\textsuperscript{(183)}.

Whereas isotopic tracers play a major role in biological research (section 8.4), measurements of isotopic fractionation per se are also very important. Some processes such as SO$_4^{2-}$ assimilation and S$^{2-}$ oxidation are accompanied by little isotope fractionation. Hence, apportioning of sources of S to plants and animals can usually be done with confidence.\textsuperscript{(139,184,185)} However under S stress, plants emit H$_2$S with a high attending sulfur KIE and IRMS of foliage can detect this process.\textsuperscript{139} This is analogous to large KIEs accompanying bacterial reduction (Equation 26):

$$\text{SO}_4^{2-} \rightarrow \text{H}_2\text{S}, \text{NO}_3^- \rightarrow \text{N}_2, \text{CO}_2 \rightarrow \text{CH}_4, \text{etc.}$$  \hspace{1cm} (26)

Although isotopic shifts between trophic levels in food webs are small\textsuperscript{(166,167)} they are nevertheless important in terms of the factors which alter them\textsuperscript{(137,141–143)} and accurate dietary reconstruction. Variations in isotopic selectivity during photosynthesis tend to be small for a given species, but the small differences can be related to temperature, humidity, and other factors\textsuperscript{(137)}.

The term ‘stable isotope geochemistry’ is commonly used\textsuperscript{(150,167)} to embrace most of the aforementioned topics. Terms such as ‘environmental isotopes’ have become part of the jargon.

### 8.6 Extraterrestrial Applications

It is fitting that IRMS should be used to examine the very processes (stellar nucleosynthesis) that generated isotopes and determined their initial abundances.\textsuperscript{(188)} The field is called ‘isotopic cosmochemistry’ which could be considered as also embracing isotopic geochemistry.

Meteorites comprise samples of extraterrestrial material with large ranges of chemical composition. Some have experienced high-temperature metamorphism, whereas others such as the carbonaceous chondrites have a low-temperature history. Their chemical/physical heterogeneity seems to have been preserved since their formation around 4.6 x 10$^9$ years ago. Four decades of IRMS of meteorites\textsuperscript{(189,190)} evolved into emphasis on fragments (submillimeter) and mineral separates. These studies have revealed many isotope abundance variations of nucleosynthetic origin.\textsuperscript{(190)} The finding of these isotopic anomalies illustrates the importance of measuring abundances for three or more isotopes of an element (section 8.1). The IRMS of meteorites has shown that the solar nebula was not completely homogenized prior to formation of the planets. Extra material, the exotic component, was added possibly from a nearby supernova explosion.

The next major step in IRMS of extraterrestrial materials was retrieval of samples from lunar missions.\textsuperscript{(191)} The primordial isotopic heterogeneities evident in meteorites, have not been found on the earth and moon presumably because of thermal obliteration. Material on the moon’s surface has been classed as crystalline rocks representing deep seated lithosphere, brecciated rocks associated with meteorite impacts, and dust/fines highly influenced by solar wind bombardment. The O- and S-isotope compositions showed less variation than those of earth. Spallation effects (interactions with cosmic rays) led to increases in $\delta^{15}$N and $\delta^{13}$C in the lunar fines. As these elements occur in relatively low concentrations, contamination during treatment is a serious issue.

Detection of isotopic anomalies at heavy masses requires large earth-based equipment. However, miniature IRMS devices\textsuperscript{(56)} transported on unmanned flights have provided informative data for light elements in the
Thus, applications of IRMS appear to be limitless, ranging from studying the functioning of micro-organisms to trying to comprehend cosmic scale events. This should not be surprising as STABLE ISOTOPES ARE EVERYWHERE!

Liquid chromatography/mass spectrometry (LC/MS) is the combination of high-performance liquid chromatography (HPLC) and mass spectrometry (MS) into a single, continuous-flow analytical system. HPLC separates analytes from their matrix and from one another in a flowing system on a time basis. These separated analytes are removed from the solvent stream and introduced to the MS system through one of several types of available interfaces which facilitate ionization of the analyte molecules. MS is an analytical technique which separates these analyte ions on the basis of their mass-to-charge ratio (m/z). Data collected from LC/MS is a series of mass spectra taken over time as the chromatographic effluent exits the column and is analyzed by the mass spectrometer. The three interface types in common usage are particle beam (PB), atmospheric pressure chemical ionization (APCI) and electrospray interface (ESI). These interfaces differ in the characteristics of the mass spectra that they produce, the types of chemical compounds for which they are best suited and the interferences to which they are subject. With the combined capability of two of these interfaces, APCI and ESI, LC/MS is able to address nearly any type of organic molecule from small molecules to biological macromolecules. ESI has ushered in a revolution in biochemical research on large molecules although the technology itself is not completely understood and is subject to a variety of interferences. APCI is limited to smaller molecules and is most at home in routine use for very high-throughput drug and metabolite analyses. The PB interface, although not as flexible as the other two, is able to produce electron ionization (EI) spectra which can be searched against standard, commercial libraries. ESI and APCI are not able to produce EI spectra but, through the use of collisionally activated dissociation (CAD), are able to produce usable spectra in both single-stage and tandem mass spectrometry (MS/MS).

1 INTRODUCTION AND HISTORY

Scientists using LC (liquid chromatography) techniques have long wished for a reliable, easy-to-use mass spectral detector. On the other hand, workers approaching this issue from the MS standpoint have always desired a direct liquid interface to the mass spectrometer which could handle samples in solution without requiring extensive sample workup. The solution to both of these problems has been the development of LC/MS. However, this is a case where the whole is certainly greater than the sum of its parts.

Both MS and HPLC (often shortened to LC) are separation techniques. In HPLC, components are separated based on their relative chemical and/or physical affinity for some type of stationary phase. This is measured as the time it takes the component to traverse the chromatographic column. This separation is represented by a ‘chromatogram’ which is a plot of detector response versus time. The separation in MS occurs on the basis of mass-to-charge ratio (m/z). The representation of this separation is a ‘mass spectrum’ which plots detector response versus m/z. (Note: it is very important always to think in terms of mass-to-charge ratio and not just mass when discussing mass spectra.)
The combination of two separation techniques can result in a technique which is not just twice as powerful but actually orders of magnitude more powerful than either technique alone. If the two techniques are completely orthogonal, in other words, they separate components based on completely different physical principles, then the ‘peak capacity’, i.e. the number of separate components the technique can theoretically resolve, is the product of the peak capacities of the two techniques. A very conservative estimate of the peak capacity of modern HPLC is 100 and that for benchtop MS is 500. If we then assume completely orthogonal separation mechanisms, the combined technique results in a peak capacity of 50 000! This is a peak capacity which is very improbable to impossible to achieve with one technique alone, no matter how many LC columns are coupled together or mass analyzers are linked.

In their landmark textbook, *Introduction to Modern Liquid Chromatography*, Snyder and Kirkland enumerate the attributes of the ideal detector for LC. Those attributes are listed here along with comments on how the mass spectrometer meets them:

- Has high sensitivity and the same predictable response (LC/MS is routinely used for picomolar or better sensitivities with excellent reproducibility).
- Has response to all solutes, or has a predictable specificity (generally, if the solute can be ionized, it can be seen in the mass spectrometer).
- Has a wide range of linearity (true for all commercially available LC/MS interfaces).
- Is unaffected by changes in temperature and mobile phase flow (true for LC/MS within typical laboratory variations).
- Responds independently of the mobile phase (generally true, although mobile phase constituents may effect ionization efficiency).
- Does not contribute to extra column band broadening (modern LC/MS interfaces, properly set up and using correct flow rates, do not present a problem).
- Is reliable and convenient to use (LC/MS is in routine use in thousands of laboratories and its use is growing rapidly).
- Has a fast response (certainly true).
- Provides qualitative information on the detected peak (this is key advantage of MS – generation of spectra which provide extensive information about compound structure).
- Is nondestructive of the solute (this is not true, at least for benchtop instruments in routine use. There are nondestructive MS techniques; Siuzdak et al.\(^1\) were able to analyze an intact virus via Fourier transform ion cyclotron resonance MS, recover the virus and use it successfully to infect a host organism).

MS meets most, if not all, of these requirements. The most significant features of MS are (1) the ability to produce ions which represent the intact molecule and can therefore give a direct and extremely accurate measure of the molecular weight of the analyte compound and (2) the ability to produce characteristic fragment ion spectra which can be interpreted to give at least partial, and often complete, structural information about the molecule.

The discussion of MS as a detection technique leads directly to the question of what sort of data are produced by an LC/MS system. Figure 1 presents a schematic answer to that question. Starting at point (a) we have a typical chromatographic peak recorded as an analog signal over time from a standard HPLC detector. A computer can digitize this signal (b) and further process that information into a report of peak areas and retention times (c). This process is familiar to chromatographers.

Mass spectral data are very different. When we connect a mass spectrometer up to the effluent from the LC column we do not obtain nice analog peaks coming off one after another. The mass spectrometer simply monitors a

![Figure 1](https://example.com/f1.png)

**Figure 1** The data generation pathways in LC/MS. (Reprinted with permission from O.D. Sparkman and F.E. Klink, *Liquid Chromatography/Mass Spectrometry Fundamentals and Applications*, ACS Short Courses, American Chemical Society, Washington, DC, 1999. Copyright 1999 American Chemical Society.)
series of \( m/z \) values and records the intensity of the ion current at each value (Figure 1d). Once this series of values has been recorded, the instrument starts over and makes another set of recordings and so on until the operator stops the data collection. These recordings may be as slow as one per second or as many as 100 or more per second, depending on the type of instrument and how it is set up. This series of \( m/z \) vs intensity data sets can be plotted as spectra such as those shown in Figure 1 at point (e). Each spectrum represents a ‘snapshot’ in time of the ions passing out of the mass spectrometer at that moment. [The three-dimensional nature of the data in (e) is also a good illustration of the orthogonal nature of LC and MS.]

Those spectra in themselves are the reason why we use MS with LC since they are very valuable for qualitative analysis of the chromatographic components. Still, they do not look much like chromatography. However, by summing all of the intensities in each spectrum we reduce each spectrum to a single point. That single point can be plotted against the time at which the spectrum was collected (f) and by a connect-the-dots approach we have a chromatogram again (a). Now, the chromatographic information can be taken into a standard chromatographic data system, via the path (a)–(b)–(c) and quantitative analysis done just as we would with other HPLC detectors.

Creating chromatographic peaks in this manner is termed ‘reconstruction’ and the resulting chromatogram is called a reconstructed total ion current chromatogram (RTICC). We may not choose to look at all of the available ion current but only selected \( m/z \) values. If we can find an \( m/z \) value (i.e. an ion) which comes only from our analyte of interest, we can plot a chromatogram based only on that one ion. This technique is called selected ion monitoring (SIM) and is a very powerful selectivity tool in LC/MS. In fact, the mass spectral data set gives us great flexibility to reconstruct dozens of different types of chromatograms and to extract tremendous amounts of useful information, all from a single chromatographic run.

Clearly, the issue holding back development in LC/MS was not mere recognition of the natural synergy between LC techniques and MS but rather the development of interfacing strategies which could bring these advantages to the average scientist’s laboratory bench. By comparison, the interfacing of a capillary gas chromatography (GC) effluent to MS was relatively straightforward. In gas chromatography/mass spectrometry (GC/MS) a high-temperature gas-phase material is introduced into a high-temperature vacuum environment. The analytes of interest are much higher in mass than the helium carrier gas and are readily separated from it by their relative momentum (see Gas Chromatography/Mass Spectrometry).

This is not so straightforward for LC/MS. An amusing illustration of this ‘odd couple’ relationship was published by Arpino\(^3\) and appears in Figure 2. The HPLC analysis lives in a solution environment at elevated pressure whereas the mass spectrometer requires a high vacuum environment with ionized gas-phase analytes. Developing a ‘meaningful relationship’ between these two is therefore a considerable challenge.

The primary problem in interfacing LC and MS is the elimination of solvent and the preservation of sufficient amounts of analyte to give reasonable detection limits. A flowing system delivering 1 mL min\(^{-1}\) acetonitrile becomes 533 mL min\(^{-1}\) of gas when vaporized at standard temperature and pressure (STP). This solvent may be carrying micrograms per milliliter or less of the analyte which must also be put into the gas phase in order to enter the mass analyzer of the MS instrument. Hence the challenge is to eliminate literally liters of unwanted solvent vapor while selectively retaining infinitesimally smaller amounts of analyte. The problem is further compounded by the fact that many LC analytes are minimally volatile or involatile and may also be thermally labile.

Two general technical approaches have been taken to produce successful LC/MS interfaces: solvent elimination/gas-phase ionization and desorption/ionization.
1.1 Development of Solvent Elimination/Gas-phase Ionization Interfacing for Liquid Chromatography/Mass Spectrometry

The first approach to solvent elimination and gas-phase ionization was the obvious approach of simply plugging an LC effluent stream directly into the mass spectrometer ion source. This direct liquid introduction technique was proposed by Talroze et al.\(^4\) in 1972 and demonstrated practically by Arpino et al.\(^5\) in 1974. The technique was limited by the very low column flow rates required (10–50 µL min\(^{-1}\)), which were impractical for HPLC applications at that time. The solvent stream was nebulized through a 4-µm orifice into a heated desolvation chamber and then into a chemical ionization (CI) source. Volatilized solvent acted as the ionization reagent. The direct inlet probe, as this interface was known, suffered from clogging of the orifice and short filament life in the CI source. Nevertheless, some basic work on pesticide analysis and biomolecules was accomplished.

In the same year that Arpino et al. publicized the direct inlet probe, Hornung et al.\(^6\) published their work on atmospheric pressure ionization (API). This technique is very similar to the direct inlet probe except that nebulization and solvent-mediated CI take place in an atmospheric pressure chamber outside the mass spectrometer. Now known as APCI, this technique is one of the most popular LC/MS techniques in use today, particularly for high-sensitivity quantitative analysis. The technique is described in detail later in this article.

The moving belt interface of McFadden et al.\(^7\) was a clever and direct approach to the issue of solvent elimination followed by analyte volatilization. Introduced in 1976, this interface was initially designed using a wire loop and later a belt which allowed greater surface area for LC effluent. The belt was moved into and out of the vacuum of the mass spectrometer by drive wheels, much like a conveyer belt. LC effluent from the end of the column or detector dripped on to the belt on the atmospheric end and then passed through a series of increasingly higher vacuum regions accompanied by mild heating which removed the residual solvent. In the final step, the belt, now with dry analyte on its surface, moved into the ion source of the mass spectrometer where the analyte was flash vaporized into the vacuum region. The belt was heated and cleaned during its return journey to the atmospheric side of the interface. Both the moving belt and direct liquid inlet could be used with a generic ion source which could accommodate other types of sample introduction, e.g. GC, when the HPLC interface as not in use.

The thermospray interface\(^8\),\(^9\) was first described in 1983 by Vestal et al. In this interface, shown in Figure 3, the LC effluent is introduced through a heated probe into a reduced pressure area (5 × 10\(^{-15}\) Torr), forming a jet of droplets. The heat imparted allows the solvent to evaporate from these droplets and to be swept out through the vacuum system. Meanwhile, ions are formed either by solvent-mediated CI or by ion evaporation processes. In the CI mode, the solvent acts as the reagent gas and is ionized by either a stream of high-energy electrons from a filament or by a corona discharge electrode. One mode or the other is selected based on the mobile phase aqueous–organic composition. Aside from operation at reduced pressure, this is the same mechanism employed in APCI. The ion evaporation mode was used with both the filament and discharge electrodes off. It is analogous to ESI, which is described later.

After the introduction of thermospray, the floodgates opened to new LC/MS interfacing techniques. The 1980s was by far the most significant decade in the history of the technique.

The PB [or monodisperse aerosol generation interface for chromatography (MAGIC)] interface was developed by Willoughby and Browner in 1984\(^10\) and has been applied to both HPLC and GC. This interface is still commercially available and popular today and therefore will be described later. At this point, it is sufficient to say that the PB system eliminates solvent through nebulization and desolvation assisted by heat and vacuum. The analyte is then ionized in a standard EI source. The PB is thus the only LC/MS interface currently available from commercial sources which is capable of producing standard EI mass spectra.

1.2 Development of Desorption/Ionization Techniques for Liquid Chromatography/Mass Spectrometry

The second technical approach, desorption/ionization, involves direct ionization of analyte from a liquid or solid
matrix without initial solvent elimination or vaporization of the analyte. The desorption/ionization techniques have had their greatest impact in the analysis of biomolecules. Since the analyte is ionized directly from a liquid or solid matrix, these techniques are not limited to the analysis of volatile molecules. Proteins, nucleic acids and other biological macromolecules are easily ionized and brought into the mass spectrometer by desorption/ionization.

A desorption/ionization technique for the analysis of static liquid samples was introduced in 1981 and termed fast atom bombardment (FAB). The technique is also known as ‘static FAB’ to distinguish it from ‘continuous-flow fast atom bombardment (CF/FAB)’, which is discussed below.) FAB relies on introduction of approximately 1 μL of sample in an involatile matrix such as glycerol. The glycerol solution is introduced on a probe directly into the MS source. The probe geometry positions the sample where it can be struck by a beam of atoms, e.g. xenon. The impact of the atom beam on the sample sputters the analytes off of the surface layer which are in turn ionized through a variety of processes. Analyte ions are then focused and directed into the mass analyzer. The glycerol matrix remains as a liquid for several minutes in the vacuum, which allows continuous production of sample ions over this time.

In 1985–86, two developments appeared which allowed the use of FAB with flowing LC effluents. The first was ‘frit FAB’ and the second was termed CF/FAB. CF/FAB relies on the same principal as static FAB but rather than using a drop of sample–matrix solution, a flowing sample is employed. The sample is flowed continuously up through the sample probe using a solution that is approximately 5% glycerol rather than the 90% glycerol matrix used in static FAB. The aqueous–organic portion of the solution evaporates quickly, leaving the glycerol matrix and sample behind. As solution is pumped through the probe, the lower viscosity of the fresh, aqueous solution forces it to the top of the bubble where it is exposed to the atom beam and is ionized. The lower percentage of glycerol reduces background interference compared with static FAB and the continuous flow allows interfacing with LC. However, CF/FAB flow rates are of the order of 5 μL min⁻¹, necessitating the use of split-flow systems with standard HPLC or the employment of micro LC or capillary electrophoresis.

Both static FAB and CF/FAB have been employed in biological macromolecule analysis. However, these techniques are being largely superseded in biotechnology applications by the desorption/ionization techniques, matrix-assisted laser desorption/ionization (MALDI) and ESI. MALDI is a static technique in which samples are prepared in a specific matrix, placed on a target or plate and allowed to dry. This plate is then placed in the ion source of the mass spectrometer where an ultraviolet (UV) or infrared (IR) laser is fired at the sample causing a type of CI between the matrix and sample molecules. Choice of matrix is one of the critical operating parameters in MALDI. The routine use of MALDI is limited to static operation although some work is under way to develop a continuous-flow version of MALDI using a moving tape interface.

Ironically, the process which today is generating the most attention in the interfacing of LC with MS is also the process which has the longest history in the literature. The electrospray process, which relies on nebulization of a solvent stream into an electrical field, was first described by Zeleny in 1917. Its applicability as a mass spectral interfacing technique was shown by Dole et al. in 1968. Dole et al. described the major advantage of the ESI technique for LC/MS, namely the ability to produce macromolecular ions. This opened the door to biological investigations using MS. ESI was introduced for bioapplications by Whitehouse et al. in 1984 and further refined for use with typical HPLC flow rates by Bruin et al.’s concept of pneumatically assisted ESI, or ionspray, in 1987. Both MALDI and ESI techniques are highly applicable to large, involatile analyte molecules and will be discussed at length later in this article.

2 LIQUID CHROMATOGRAPHY CONSIDERATIONS FOR MASS SPECTROMETRY

The technique of HPLC is truly the analytical technique of the 20th century. Michel Tsvet’s seminal paper first describing liquid–solid partition chromatography appeared just after the turn of the 20th century. Martin and Sygne’s Nobel Prize-winning work in 1941 described much of the theoretical foundation for later HPLC developments. It was not, however, until the late 1960s that high-pressure pump hardware became available to the analytical community at large and it was from this point that HPLC use started a meteoric rise. Majors’ development of microparticulate bonded phases in 1972 allowed the technique rightfully to take on the name ‘high performance’. In less than 20 years, the use of HPLC grew from a curiosity to the most widely used analytical technique in the world. Its applications span all forms of chemical and biological research, biomedical applications, environmental analysis and nearly every industrial application of chromatography. While the analytical use of HPLC is the most widespread, there is a very large segment of the user population who take advantage of the nondestructive nature of the technique for preparative applications (see the entries in Liquid Chromatography).
Most present-day users of analytical HPLC employ 3–4.6 mm inner diameter (ID) columns using solvent flow rates of 0.5–2 mL min\(^{-1}\). Growing interest is seen in ‘fast’ LC columns, i.e. shorter length columns but still of ~4 mm ID\(^{24}\). This has remained the case for over 20 years in spite of the development during that time of micro-HPLC. The development of the ‘micro’ technique began with smaller diameter columns of 1 or 2 mm ID up to the present day when nano-LC columns may be of <100 µm ID. In the last few years, the major HPLC manufacturers have begun to produce high-performance pumps to deliver solvents accurately at the lower flow rates required by these columns. However, to switch over to the micro-LC techniques requires replacing nearly all of the components of the HPLC system. Extra-column band-broadening effects from the internal volumes of tubing and injection systems which are not suited to small-diameter columns will compromise the results of analyses. Analytical results may, in some cases, be poorer with small diameter columns if these hardware issues are not taken into account.

HPLC’s success is the very thing which holds back its rapid technological evolution in the average analytical laboratory: the financial investment required to replace outright many thousands of dollars worth of equipment is not justified by solvent or sample savings realized by use of micro-HPLC techniques.

LC/MS may change this picture. ESI/MS and APCI/MS are highly sensitive techniques which have no difficulty detecting the very small amounts of sample introduced through micro-HPLC columns. Even more important, micro-flow rates actually improve electrospray performance and sensitivity. The electrospray technique was originally developed for use with very low flow rates. Subsequent developments in ESI (such as ionspray described earlier) focused on adapting the technique to higher flow rates but this came at the cost of performance. With the development of practical micro-HPLC systems, users are rediscovering the outstanding performance of ESI as a low-flow technique. This and other aspects of low-flow-rate HPLC will be discussed later.

There are three basic LC hardware configurations for interfacing a flowing liquid effluent to an MS interface, as illustrated in Figure 4(a–c). Figure 4(a) shows the simplest configuration of flowing liquid interface. A simple pump, e.g. a syringe pump, drives liquid sample directly into the MS interface. This is referred to as continuous infusion or simply infusion. This technique is very useful in method development because it can be used to provide a continuous background of the analyte spectrum in the mass spectrometer. This allows tuning of the mass spectral conditions and flow rate without having to make multiple injections. If a pump is used which is capable of multisolvent proportioning, this technique can also be used to study the effects of various solvent systems on ionization efficiency. The new protein analysis technique called nanospray employs continuous infusion for analytical use and will be discussed later.

Figure 4(b) shows the next step up in complexity. A standard analytical HPLC pump plus an injection valve replace the continuous-flow pump used for infusion. Sample is now introduced by injection into the flowing solvent stream and hence this technique is known as flow injection. This technique is also very useful in method development because the effect of different injection volumes, solvents and concentrations on analyte ionization efficiency can be quickly evaluated. It is also ideal for observing the mass spectral effects of changing mobile phase solvents, additives, pH, etc. without worrying about their impact on a chromatographic separation. It may, in fact, be possible to use this technique in the final analytical method if column separation of the analytes is not required. For example, analytes which are clearly separated by mass-to-charge ratio (m/z) in the mass spectrum can be readily distinguished and quantified without further separation. Qualitative information can also be obtained in this case by the employment of MS/MS in which a single ion representing the intact analyte molecule is subjected to a second stage of MS where fragmentation occurs. This fragmentation gives a pattern characteristic of the structure of the molecule (see Tandem Mass Spectrometry: Fundamentals and Instrumentation). A standard HPLC autosampler may be employed in place of the injection valve for high throughput, automated analyses.
The final technique (Figure 4c) involves the use of a complete HPLC system including an analytical column for interface to the MS. For many closely related compounds, e.g. drugs and metabolites, it is not possible to obtain sufficient separation by MS alone. In these cases, an HPLC column separation is required. In other analyses, interferences present in the sample matrix may suppress ion formation of the analyte (ion suppression effects will be described in more detail at the end of this article). Again, an HPLC column separation of matrix components from analyte prior to the MS interface will solve this problem. The HPLC separation can sometimes be compromised because of the additional separation power of the MS. This is becoming increasingly clear in the area of sample preparation. In many recent applications using short columns or solid-phase extraction (SPE) cartridges, it is not so easy to distinguish the ‘sample preparation’ step from the ‘chromatographic’ step.\(^\text{25}\)\(^\text{25}\)

In Figure 4(c), a hardware component has been added after the column and before the MS interface to allow postcolumn modifications to the solvent stream going into the mass spectrometer. The solvent system needed for the HPLC separation may be incompatible with the MS interface. Postcolumn modifications to the solvent stream are then employed to optimize the ionization efficiency.

3 MODERN METHODS OF INTERFACING LIQUID CHROMATOGRAPHY EFFLUENT WITH MASS SPECTROMETRY

In the Introduction, a brief history of the development of LC/MS interfacing techniques was presented. Three significant techniques have survived to the present day and represent most of the technical literature and all of the available commercial instrumentation. The PB interface and APCI rely on volatilization of solvent and analyte followed by gas phase ionization. ESI works on the principle of desorption/ionization and is therefore capable of handling large, involatile analyte molecules.

3.1 Particle Beam Interface

The only currently available commercial PB interface is the Waters Thermabeam™. The PB interface as originally designed required high flow rates of nebulizing gas and exhibited very poor sensitivity in comparison with other LC/MS techniques such as APCI and ESI. The introduction of the Thermabeam™ interface addressed both of these problems primarily through use of a heated nebulizing chamber. Sensitivities in the low-nanogram range are routinely seen with this instrument. Although APCI and ESI are still more sensitive techniques, PB has the advantage of producing true EI spectra. Research work has been done with a micro-PB interface\(^\text{26}\) in an attempt to improve sensitivity. Sensitivities of <1 ng have been reported using LC effluent flow rates of 1–5 µL min\(^{-1}\).

Figure 5 is a schematic diagram of a PB system. The LC effluent is sprayed through a 5–10 µm ID orifice. This results in the formation of a fine liquid jet which forms a stream of uniformly sized droplets. A stream of high velocity gas, usually He, is introduced at 90° to the liquid jet and serves to disperse the liquid into a fine aerosol. The first step in the interfacing process is the elimination of mobile phase solvent which is vaporized at atmospheric pressure in a ‘desolvation chamber’. Under ideal conditions, all of the mobile phase is vaporized, and the analytes remain as a semisolid or less volatile liquid droplet (colorfully referred to as ‘dirty snowballs’). The solvent vapor and analyte molecules pass through a two-stage momentum separator to produce a PB of analyte. This PB then strikes a heated plate in the ion source to produce the gas-phase molecules. These molecules rebound off the plate to be ionized by a 70-eV electron beam in a conventional EI source. As with other EI techniques, the ions formed from intact molecules are typically odd-electron species, M* or M-.

An EI source operates, by convention, at 70 eV. This level of ionizing energy ensures the maximum possible ionization efficiency. Figure 6 shows ion current produced by varying levels of ionization energy. In region A of the curve, the only ions formed are molecular ions. In region B, some fragmentation begins to occur owing to the higher energy imparted to the ions. Finally, in region C, the ion current has reached its maximum. In this region, significant amounts of fragment ions are formed from decomposition of molecular ions and it is these fragment ion spectra which provide structural information about the molecule. Operation at 70 eV ensures that spectra will be collected well into the C region for all molecules. At 70 eV, molecules of a given type will always yield ions with the same energy distribution and therefore the same fragmentation patterns and fragment relative abundances. These are the spectra which are
considered ‘standard’ mass spectra and are available in a variety of commercial databases and search engines. PB is the only LC/MS interfacing technique which yields standard EI mass spectra. (See Electron Ionization Mass Spectrometry.)

CI sources have also been used with the PB interface, although no commercial products are currently available. CI will typically result in a far less complex spectrum than is seen with EI. Often these spectra contain only one ion, that being one which represents the intact molecule which provides information about the molecular weight of the molecule but no structural information. CI will be discussed in detail in section 3.2.1.

PB is ideal for those molecules which cannot survive the high-temperature environment of a gas chromatograph but are still volatile enough to go into the gas phase at moderately elevated temperatures. Because of the volatility requirement, PB is limited to analytes of molecular weight $\leq 1000$ Da. Natural product molecules, steroids and carbamate pesticides are good examples. PB is also an excellent companion technique to photodiode array (PDA) detection. PDA data allow the analyst to determine the areas of maximum chromatographic peak purity and therefore the best portions of the chromatogram from which to obtain EI spectra. This allows for the collection of good, library-searchable spectra from less-than-ideal chromatography. Of course, a PDA detector also has this advantage for use with other LC/MS interfaces.

3.2 Atmospheric Pressure Ionization Interfaces

The most widely used LC/MS interfacing techniques are currently the API interfaces, namely the APCI interface and ESI. Figure 7 illustrates both of these variations of the API concept and serves to show that there are more similarities than differences in these two techniques. When these interfaces first appeared they were thought of as little more than ‘molecular weight machines’ because they produce only ions derived from the intact analyte molecule. The ionization process, unlike EI, does not impart sufficient energy to cause fragmentation and therefore no standard set of spectra can be generated. However, CAD does allow for fragmentation and these fragmentation patterns can be interpreted in qualitatively meaningful ways.

3.2.1 Atmospheric Pressure Chemical Ionization

The first LC/MS technique to gain widespread acceptance for routine analytical work was the APCI interface. APCI has extremely high sensitivity, is simple to use and is very rugged in high-throughput operation. When coupled with MS/MS, the technique provides excellent quantitative sensitivity and high specificity. Based on these performance characteristics, APCI is the method of choice for open access LC/MS systems. Open-access systems are specifically designed for analysts with little MS experience. These users need only set a couple of simple method parameters to process their samples and obtain usable mass spectral data.

CI is a reaction between a reagent ion and an analyte molecule in the gas phase. APCI uses the vaporized LC mobile phase (solvent) as the CI reagent. It is therefore not necessary in APCI to add a CI reagent from an external source as is required with GC/MS.

Referring to Figure 7, the APCI inlet is shown at the bottom left. The LC effluent flows in from the left side of the diagram through a capillary inlet needle. This needle is surrounded by a second needle carrying nebulizer gas resulting in a nebulized spray of LC effluent being introduced into the interface at atmospheric pressure. A heater at the outlet of the nebulizer assembly ensures vaporization of the LC solvent and analyte molecules. APCI interfaces are generally operated from 150 to as high as $400^\circ$C depending on the volatility and thermal lability of the solvents and analytes. The temperature of the interface is an important method parameter since analyte volatility is essential to the APCI process. A potential difference of $\sim 3–5$ kV is set between the capillary nebulizer and the inlet to the mass spectrometer. The sign of this potential determines whether positive or negative ions will be drawn into the mass analyzer.

Just beyond the outlet of the capillary nebulizer assembly is a corona discharge needle. A high voltage applied to this needle leads to the formation of a corona of ionized atmospheric gas around the needle. Mobile phase vapor passing through this corona is ionized, e.g. $\text{H}_2\text{O} \rightarrow \text{H}_3\text{O}^+$. Further down the path to the mass...
Figure 7 Schematic diagram of generic API interface showing both APCI configuration (bottom left) and electrospray (top left). The mass analyzer (far right) is shown here as a transmission quadrupole but may also be a quadrupole ion trap, time-of-flight (TOF) or magnetic analyzer. (Reprinted with permission from O.D. Sparkman and F.E. Klink, Liquid Chromatography/Mass Spectrometry Fundamentals and Applications, ACS Short Courses, American Chemical Society, Washington, DC, 1999. Copyright 1999 American Chemical Society.)

spectrometer inlet, gas-phase ion–molecule reactions take place which result in the formation of analyte ions. This process is also called solvent-mediated CI. For example, in the analysis of an amine RNH₂, the CI reaction may be as shown in Equation (1):

$$
\begin{align*}
\text{H}_3\text{O}^+ + \text{RNH}_2 & \rightarrow \text{H}_2\text{O} + \text{RNH}_3^+ \\
\end{align*}$$

The ionized analyte is taken into the mass analyzer and the neutral water molecule is swept out through the vacuum system in the first pumped low-pressure region of the MS inlet.

The modes of ionization common in CI are represented in Scheme 1, in which M represents the analyte molecule.

The formation of even-electron ions by protonation, proton abstraction and adduct attachment is by far the most common APCI ion formation reaction scheme. It is important to note that in each case the resultant ion has a mass different from the analyte molecule. These ions are therefore not referred to as molecular ions but as ions which represent the intact molecule. Fragmentation of these ions is possible using CAD. CAD fragmentation may occur prior to entry into the mass analyzer or in a collision cell which is part of an MS/MS system. CAD will be discussed in more detail at the end of this section.

Scheme 1

In order to obtain the best results from APCI, it is necessary to understand something of the mechanism of the gas-phase ion–molecule reactions. Figure 8(a) and (b) shows the common HPLC solvents and analyte functional groups and their relative ionization potentials. Figure 8(a) shows positive ion operation. During the gas-phase ion–molecule reactions protons will, in effect, transfer downward in this chart, i.e. toward the formation of the weakest acid. Therefore, the molecule with the highest proton affinity will show the greatest ionization efficiency. If this molecule is a mobile phase component,
ionization of the analyte molecule will be completely suppressed owing to the much greater abundance of mobile phase compared with the analyte. On the other hand, if the molecule of higher proton affinity is a sample component, a better HPLC separation of this component from the analyte or a different sample preparation procedure will solve the problem. Figure 8(b) shows the corresponding chart for negative ion operation. In this case, the APCI reaction goes toward the weakest base.

APCI works well for most small molecule analytes, even those which contain no acidic or basic sites (e.g., alcohols, aldehydes, esters, ketones and hydrocarbons). The analyte must be volatile and proper setting of the capillary nebulizer heater temperature is important. It must be sufficient to volatilize the solvents and analytes but no so high as to decompose them thermally. APCI, along with PB, is essentially a small molecule interface. The upper limit of analyte mass in APCI is around 2000 Da. The lower limit is approximately 150–200 Da owing to low mass noise in the spectra. This low mass noise is a result of solvent ions taken into the mass analyzer along with the analyte.

APCI is extremely sensitive. The ionization efficiency is the best of all interfaces discussed in this article and can approach 100% of the analyte introduced into the interface, of which approximately 1% reaches the MS detector. Routine sensitivities in the low-picogram range are observed and femtogram limits of detection are not uncommon.

### 3.2.2 Electrospray Interfacing

ESI is the second API technique, along with APCI. The hardware for ESI has much in common with APCI and, in fact, modern instrumentiation is easily switched between these two ionization modes. In ESI, as in APCI, a capillary needle sprayer introduces sample into the atmospheric pressure interface (Figure 7). An electric potential is again applied across the capillary needle and the entrance to the low-pressure region of the mass analyzer. However, in ESI there is no corona discharge needle and temperatures are not as high as those used in APCI.

The first important consideration in understanding ESI is the nature of the ionization process. In all other interfacing techniques discussed in this article, ionization takes place in the interface. Hence all of these other techniques have the term ‘ionization’ in their name. Electrospray is different – ions must exist in solution for the electrospray process to work as a mass spectral interface. Consequently, it is properly referred to as an electrospray interface, not electrospray ionization.

It is convenient to think of the ESI process as an electrochemical cell which operates in the gas phase. The circuit is composed of the capillary needle and the...
inlet to the mass spectrometer (across which the potential is applied) and is completed by the ionic LC effluent solution. Figure 9 shows an ESI producing positive ions. Negative counterions are depleted from solution in the oxidation process at the positively charged capillary sprayer. LC effluent droplets, now with an excess of positive ions, draw out of the tip of the capillary in a characteristic ‘Taylor cone’ formation and are pulled in a thin jet toward the negatively biased MS inlet. There are a number of competing theories about exactly how ions are evaporated from the surface of the liquid, \(^{18,30–32}\) but each of these theories shares some common elements. It appears that as a droplet moves toward the MS inlet it breaks down into a series of successively smaller droplets as the neutral solvent molecules are evaporated. This process is aided by the charge repulsion of the like-charged ions clustered on the surface of the droplet. The entire process is called ion evaporation. Eventually, only partially solvated ions remain to be taken into the mass analyzer where the remaining vaporized solvent is swept out through the vacuum system of the instrument.

Since very low energy is applied in ESI, no fragmentation takes place. ESI typically produces even-electron protonated (+), deprotonated (−) or adducted (+ or −) species representing the intact analyte molecule (see section 3.2.1 for an explanation of these ion types). Formation of these ions is facilitated by control of the pH of the solution as it is introduced into the interface. \(^{28,29}\) The chromatographic conditions, however, may preclude adjustment of the mobile phase pH to the required value. In this case, a postcolumn introduction of acid or base can be used to adjust pH prior to the ESI inlet. \(^{33}\) Ion suppression resulting from acid–base ion–molecule reactions in the gas phase which were noted for APCI (Figures 8a and b) are also of concern in ESI. A discussion of interferences and suppression effects is included at the end of this article.

Electrospray has two key characteristics which make it ideal for the analysis of biological macromolecules: (1) nonvolatile analytes can be passed into the mass spectrometer using ESI and (2) multiply charged ions can be produced by ESI. These characteristics, taken together, allow very large biomolecules to be introduced to the mass spectrometer and permit them to be seen at reasonable \(m/z\) values well within the range of the mass analyzer. For example, with ESI it is possible to analyze a protein of 10,000 Da using a mass analyzer which has an upper \(m/z\) limit of 3000. The electrospray ionization process facilitates putting this large, ionized molecule into the mass spectrometer. Second, if the molecule is capable of carrying, let us say, 10 charges, then the peak representing the ion will show up at \(m/z = (10000 \text{Da}/10 \text{charges}) = 1000\).

Usually, however, biological macromolecules do not appear in the spectrum as a single peak but rather a cluster of peaks representing ions of different charge states. These clusters are characterized by a one-charge difference between adjacent peaks. The analyst can ‘tune’ the number of charges and the spectral positioning (in terms of \(m/z\)) of these peak clusters by altering the pH of the analyte solution. Deconvolution algorithms are used to interpret these multiple peak clusters and present the results on a mass (as opposed to an \(m/z\)) scale. The result is an artificial spectrum of the macromolecule as a singly charged ion. Because the deconvolution is based on many multiply charged ion peaks, a very accurate mass for the singly charged ion and, consequently, for the molecule can be determined. \(^{29}\) Figure 10(a–c) shows a typical multiply charged ion cluster and the results of two different deconvolution approaches. Spectrum (a) represents the data obtained from the instrument. Each peak represents an ion of the intact rho protein (47,005 Da) and adjacent peaks differ by one charge. These ions carry charges in the range +70

Electro spray as used in LC/MS can be characterized as a concentration detector, meaning that the response is directly proportional to the concentration of analyte in the solution sprayed into the interface. The linear range of ESI is from $10^{-9}$ to $10^{-5}$ M. From $10^{-5}$ to $10^{-4}$ M the signal increases with approximately the square root of concentration and above $10^{-4}$ M the signal begins to decrease with increasing concentration. (30) Most detectors in HPLC are mass detectors, in which the response is proportional to the mass of analyte introduced. For mass detectors, a larger injection volume creates more signal. With an ESI concentration detector, an increased injection volume will have no effect on response. This is important information for method development where either concentration or dilution may be necessary to optimize the signal for a particular analyte.

The original descriptions of electrospray for MS (18) and for LC/MS (19) showed the technique to be limited to flow rates of the order of 1–10 µL min⁻¹. This technique used a simple capillary sprayer as illustrated in Figure 11(a). These low flow rates were not practical for routine chromatography until very recently. Ionspray (20) was developed in 1984 to overcome the low flow rate limitation. This modification is illustrated in Figure 11(b) and consists of a second needle concentric with the inlet capillary. A gas flow is introduced through this second needle and acts to nebulize the incoming liquid to +40. Spectrum (b) results from a simple deconvolution algorithm and spectrum (c) was generated using a more sophisticated ‘maximum entropy’ method which allows resolution of isotope peaks. (34)
flow. A further refinement of this approach was to add a heater (Figure 11c), resulting in a technique known as turbospray. Both turbospray and ionspray allow the use of ESI with typical analytical HPLC flow rates of up to 1 mL min\(^{-1}\). Variations of these two nebulizer-assisted techniques are used in all current commercial ESI products.

With increasing interest in micro-flow rate HPLC techniques and the increased availability of HPLC pumps and accessories for micro-techniques, a corresponding surge in interest in low-flow rate ESI is occurring. Beginning in 1995, Andrén et al. demonstrated use of a minaturized, nebulizer-assisted electrospray coupled with a micro-HPLC system operating at flow rates of 300–800 nL min\(^{-1}\). This device, called micro-electrospray, is not a return to the original ESI design but a miniaturization of the ionspray concept. These researchers demonstrated optimum ESI sensitivity in the zeptomole and attomole range, improved performance with high-aqueous solvent systems and reduced contamination.

In parallel with Andrén et al.’s work, Wilm and Mann developed the concept of nano-electrospray or, simply, nanospray. This interface uses backing gas pressure in place of a mechanical pump to drive solvent into the interface. Very small ID capillaries (1–2 \(\mu\)m) are used and operation is carried out at very low flow rates, of the order of 20 nL min\(^{-1}\). No nebulization is used and therefore this method can be thought of as a ‘pure’ electrospray method. Nanospray was originally developed as a continuous infusion method for protein analysis. By infusing sample continuously over a period of many hours, thousands of spectra are collected and averaged. This improves the signal-to-noise ratio and allows for very accurate \(m/z\) determination and high spectral resolution. For unknown protein samples, this results in excellent sensitivity and remarkably accurate exact mass determinations while consuming very little sample. More recently, this technique has been expanded to use nano-HPLC columns to achieve some degree of initial separation, although not with high chromatographic resolution. Nanospray routinely exhibits femtomole and better sensitivities.

Commercial products for both micro- and nano-ESI are becoming widely available at the time of this writing. The use of micro-diameter columns results in very narrow chromatographic peak widths and this in itself presents data acquisition problems for the mass spectrometer. Typical benchtop LC/MS systems employing transmission quadrupoles or quadrupole ion traps are limited to spectral data acquisition rates of 1–10 spectra per second. This is inadequate to obtain a sufficient number of spectral samples across the very narrow peaks typical of micro-HPLC. Consequently, commercial micro- and nano-ESI products are linked with time-of-flight (TOF) mass spectrometers. TOF instruments have spectral data acquisition rates of 100 spectra per second or higher. In addition, modern reflectron TOF instruments exhibit very high spectral resolution, excellent \(m/z\) accuracy and virtually unlimited \(m/z\) range. (See Time-of-flight Mass Spectrometry.)

Electrospray (in its several forms) is ideally suited to analytes which can be readily ionized in solution, are marginally volatile or involatile and/or would thermally decompose at the higher operating temperatures of the other LC/MS interface types. Ion suppression effects (discussed below) must be understood and appreciated or poor performance could result. Electrospray generally works well with aqueous solvent systems and, since there is no concern about involatile analytes, this interface is the ideal companion to reversed-phase or aqueous size-exclusion chromatography. The sensitivities for modern electrospray systems approach that for APCI and ESI can be considered nearly on a par with APCI for ruggedness and ease-of-use. The most rapidly evolving area for electrospray is in biological macromolecule analysis (see Capillary Electrophoresis/Mass Spectrometry in Peptide and Protein Analysis: High-performance Liquid Chromatography/Mass Spectrometry in Peptide and Protein Analysis and Mass Spectrometry of Nucleic Acids).

### 4 COLLISIONALLY ACTIVATED DISSOCIATION IN LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY

The CI process in APCI and the ion evaporation process in ESI produce only ions of the intact analyte molecule. If this were the only capability of these two techniques, they would still be very useful in the determination of exact molecular weights and in the separation of analytes of different mass which could not be separated by the chromatographic process. However, through the process of CAD, it is possible to produce fragment ions and to apply mass spectral interpretation techniques to the fragment ion spectra to yield qualitative information about the analyte molecule. Collision-induced dissociation (CID) is a widely used synonym for CAD.

The CAD fragmentation process takes place after ions have been formed. This process is the basis for fragmentation in all forms of MS/MS regardless of the nature of the front-end interface to the mass analyzer (see Tandem Mass Spectrometry: Fundamentals and Instrumentation). In API interfaces another CAD option is available which is called ‘up-front’ or ‘in-source’ CAD.
In this instance CAD fragmentation takes place before the ions enter the mass analyzer ion optics. This region is labeled ‘CID region’ in Figure 7.

Note that this region is just before the skimmer cone, the first element of the ion optical system. Ions traversing this region of relatively high pressure (at least 10^{-4} Torr) are likely to collide with neutral gas molecules. If the collisions are sufficiently energetic, this increases the internal energy of the ions. To shed this excess energy, these ions will fragment. The velocity with which ions traverse the CAD region is controlled by the voltage applied to the skimmer. The voltage at which fragment ions begin to appear varies with analyte compound and the API system design.

Figure 12(a–d) illustrates up-front CAD fragmentation of the metabolite desmethylcitalopram at various voltages applied to the skimmer cone (see Figure 7). Referring to Figure 12(b), at 20 V there is no fragmentation evident. The single peak at m/z 311 is the M + H ion as shown in Figure 12(a). At 50 V (Figure 12c) there is now considerable production of fragment ions, as seen by the appearance of peaks at lower m/z values. If we were to examine actual ion abundances, not the relative intensity shown here, we would find that the absolute amount of the m/z 311 ion has dropped as the fragment ion abundances increased. Finally, at 80 V (Figure 12d) there is no M + H present and even the larger fragment ions have dropped in abundance relative to the m/z 109 fragment ion. This accelerating voltage is enough to decompose all desmethylcitalopram ions into very low-mass fragments.

The CAD processes in MS/MS and in up-front CAD are very similar. In up-front CAD, the gas molecules are largely nitrogen from the atmosphere or from the sweep gas used in some interfaces to aid solvent evaporation. In MS/MS, gases such as argon or helium are introduced to the collision cell to function as CAD gases. Up-front CAD and MS/MS can also produce very similar spectra. With MS/MS the analyst has the advantage of selecting only certain ions for fragmentation. Therefore, MS/MS can generate usable spectra even if the chromatographic separation has not resulted in a pure compound. Up-front CAD fragments all ions passing into the analyzer, which means that interpretable spectra can only be obtained if pure compounds are introduced to the API interface.

As described earlier, both APCI and ESI produce primarily even-electron ions, e.g. [M + H]^+. EI spectra, such as those from GC/MS and PB interfaces, produce odd-electron species, M^+ and M^+. Classical MS interpretation rules are based on the radical site-initiated fragmentation of these odd-electron ions. Even-electron ion fragmentation can therefore result in different fragments being produced than are seen for the same compound in EI. The ‘even-electron rule’ states that the neutral loss from an even-electron ion will tend to be the fragment with the lowest proton affinity and, as a consequence, the charge will be retained on the fragment with the highest proton affinity. Rearrangements and multiple-bond cleavages are common in CAD spectra. (See Electron Ionization Mass Spectrometry for EI spectral interpretation and Atmospheric Pressure Ionization Mass Spectrometry for API spectral interpretation.)

Interpretation of CAD spectra can be further complicated in electrospray by the production of multiply charged ions. Fragments of multiply charged ions will carry fewer charges than the intact ion and therefore may appear at similar or even higher m/z values than the ion from which they originated. Data system software which not only deconvolutes multiply charged ion spectra but...
also identifies fragment ions in these spectra is a necessity for biospectrometry with ESI/MS.

A unique use of both up-front CAD and MS/MS with ESI has been the work on sequencing of proteins and nucleic acids. Both of these biomolecules fragment in CAD in ways that can be interpreted to give at least a partial sequence of their component amino acids or bases. Specific software products are available to support CAD sequencing of biomolecules. (See *Mass Spectrometry in Structural Biology; Mass Spectrometry of Nucleic Acids and High-performance Liquid Chromatography/Mass Spectrometry in Peptide and Protein Analysis*.)

EI spectra have long been used for exact qualitative analysis through the comparison of an unknown spectrum with libraries of spectra of identified compounds. Such libraries are available for drugs, metabolites, toxins, pesticides, environmental pollutants and their common GC derivatives. Because of variations in the HPLC environment from one analytical method to another and design variations from one interface manufacturer to another, it is not possible to create similar ‘standard’ libraries for CAD spectra using LC/MS and API interfaces. However, within the confines of a defined LC/MS method, users have been successful in creating libraries of CAD spectra and using these in routine identification of unknown spectra using both up-front CAD and MS/MS. One recent report described the creation of a 400-compound library of drugs and the use of this library to evaluate patient samples. In all of these papers libraries were devised on the basis of two or more spectra from each compound taken at different applied voltages as shown in Figure 12(b–d). Excellent reproducibility of CAD spectra from one instrument to another instrument of the same model and manufacturer was also reported.

5 SAMPLE AND SOLVENT CONSIDERATIONS IN METHOD DEVELOPMENT

Components of the sample matrix or the chromatographic mobile phase may have an adverse effect on the results from an LC/MS analysis using API interfaces. Analysts must understand these potential adverse effects and the various means of controlling them. Although there is considerable overlap, it is convenient for this introductory discussion to place these effects into four categories: spectral interference, system compromise, adduct formation and ion suppression.

5.1 Spectral Interference

Ions which appear at the same or nearly the same m/z value as the component of interest will interfere with both qualitative and quantitative use of the spectrum. Ions of similar m/z value can generally be separated by the chromatographic process prior to entry into the mass spectrometer. Where this is not possible, a clear distinction can often be made between the components through use of selected reaction monitoring (SRM) with an MS/MS system. Finally, newer LC/MS systems employing TOF mass analyzers are generally able to distinguish much better than unit mass resolution and can therefore ‘pull apart’ spectral peaks which may show considerable overlap in lower resolution systems.

5.2 System Compromise

Many ‘classical’ mobile phase components used in HPLC may degrade the performance of the LC/MS system. Chromatographers approaching LC/MS for the first time must begin to switch their thinking from concepts related primarily to UV detectors and toward mass spectral considerations. Components of the mobile phase which are likely to precipitate in the API interface are generally buffer salts or ion-pair reagent salts. Phosphate buffers became the pH control system of choice in HPLC because they are usable down into the very low UV detection wavelengths. Obviously, this is not an issue for an MS system. In some cases, substitution with volatile buffers, e.g. ammonium acetate or formate, will be a reasonable approach. For very high sensitivity analysis in electrospray, both of these buffers have been shown to contribute to signal suppression.

However, in most HPLC separations, buffering capacity is not required at all. Buffer salts may be eliminated in favor of the use of organic acids or ammonia solution to control pH.

5.3 Adduct Formation

Adduction of another ion with the component of interest, shifting the m/z value at which it appears in the spectrum is common with API interfaces. Adduct ions such as sodium, potassium and ammonium may be readily picked up from the sample itself, from reagents used, or the container in which the sample is held (Na⁺ from laboratory glassware is the most common example). Adduct formation in MS has often been used to improve sensitivity, especially for macromolecules. However, uncontrolled adduct formation is generally undesirable and requires specific sample preparation procedures to reduce or eliminate it. SPE methods on reversed-phase and ion-exchange sorbents are widely used for the removal of salts and buffers which contribute to ion suppression effects and adduct formation. Naturally, many SPE and chromatographic procedures have the potential for integrated, automated operation with the LC/MS instrument.
5.4 Ion Suppression

Components of the sample or chromatographic mobile phase may suppress ionization of, or compete in the ionization process with, the analyte of interest. Ion suppression is the most critical of the four types of interference because it is often the most difficult to determine. For both qualitative and quantitative LC/MS work with API interfaces, understanding and eliminating ion suppression effects are essential.

The formation of ions in API interfaces through gas-phase ion–molecule reactions was described earlier. One of the more common types of ion suppression results from the presence of a large excess of a compound with greater proton affinity (+ ion operation) than the analyte of interest. In the vapor phase of the API interface this compound will be preferentially ionized. Figure 8(a–b) should be referred to for an understanding of these processes for both positive and negative ion operation.

Ion suppression effects due to mobile phase components will generally be easy to diagnose and eliminate during the methods development process. Use of the previously described flow injection technique (Figure 4b) allows the analyst a wide playing field for experimenting with the effects of various mobile phase components. Both standards and actual samples should be run during these experiments.

Components of the sample matrix, some of which do not show up in the mass spectrum in the m/z range being investigated, can also cause ion suppression. In biological samples, natural variations in endogenous compound concentrations from one sample to another lead to varying levels of ion suppression. This, in turn, contributes to unacceptable variability in the signal response for the compounds of interest. The solution for these cases is found in better chromatographic separation of analytes from interferences or improved sample preparation procedures.

Another type of ion suppression is thought to occur when very strong ion pairs are formed which are not broken apart by the conditions in the API interface. The simplest solution is to eliminate the ion-pairing agent. This may shorten retention times, cause peak overlap and/or degrade peak shape but these issues are often not critical with LC/MS since usable spectral information may still be obtained from ‘poor’ chromatography. Ion-pairing agents which often cannot be eliminated are trifluoroacetic acid (TFA) and heptafluorobutyric acid (HFBA) in peptide/protein and other complex molecule analysis. TFA and HFBA are thought to improve peak shapes in reversed-phase chromatography by ion pairing with basic sites on the molecule, thereby eliminating mixed retention mechanisms. However, TFA ion pairs are not broken up in the mild conditions of ESI and this prevents ion evaporation of the unpaired analyte ion. The problem can be reduced by limiting the concentration of TFA to <0.1% or using ‘TFA light’, which is a reduced amount of TFA, perhaps 0.05%, and the same concentration of acetic acid. This serves to control pH and promote ionization, as required for electrospray, without forming an abundance of ion pairs.

REFERENCES

The mass spectrometry (MS) literature is one of the major sources available for keeping up to date with new developments in the technique. There are different ways of reporting and presenting MS information, such as journals, abstracts and books, and several different means of distribution, including printed, diskette, CD-ROM and the Internet.

1 INTRODUCTION

MS has grown to be one of the most important and powerful analytical techniques available today and the value of the literature in the advancement of the technique cannot be underestimated. Although many major developments in MS have been reported at conferences and symposia, most are recorded for posterity in the printed literature. This article examines the various currently available literature sources and their distribution media, including primary journals, secondary (abstracts) journals and books, published in printed, diskette, CD-ROM and Internet formats. Other Internet-based literature resources are also discussed. A compilation of MS books with brief descriptions of their content is presented.

2 PRIMARY JOURNALS

A primary scientific journal is defined as one that publishes original research work, whereas a secondary journal contains original information from one or more primary journals that may be in the form of abstracts or other summaries. The number of primary journals related to chemistry is increasing regularly, with new journals appearing each year and very few journals being discontinued. This rise, combined with the increase in the numbers of papers published within the journals, is illustrated clearly in the average number of papers (excluding patents and books) abstracted by Chemical Abstracts over comparative 4-year periods. In 1983–86, the average annual number of abstracted papers was 379 078. In the period 1995–98 this average was 571 686. For journals specializing in MS, the same pattern is visible, and these primary MS journals are a major resource for the mass spectrometrist, both in keeping pace with new developments and applications and, to a lesser extent, for retrospective research.

2.1 Printed Form

Since the first journal devoted to MS was published (Journal of the Mass Spectrometry Society of Japan, JMSSJ, Tokyo, Japan, 1953) several new MS primary journals have been launched, most recently European Mass Spectrometry (EMS, IM Publications, Chichester, UK) in 1995, and some have been amalgamated, but none have been discontinued. This popularity of the MS literature reflects the way that the MS technique has become a routine laboratory tool over the last two decades. It also mirrors the development and application of the newer MS techniques such as electrospray ionization and matrix-assisted laser desorption/ionization (MALDI), which have become relatively affordable to most laboratories and have opened up the biological and (bio)polymer areas of science to MS. This, in turn, means that we find many significant papers on MS in “non-MS” journals that deal primarily with biochemistry or biology, far more so than in the mid-1980s when electron ionization and chemical ionization were the most common MS techniques.

There are several journals dealing exclusively with MS, as detailed in Table 1. Most of these are fully referred or sponsored so that the quality is assured. However, there
are different philosophies behind some journals, involving criteria such as speed of publication and content.

The first journal on MS was published in Japan by the MS Society of Japan and began in 1953. Named Mass Spectrometry, it was retitled Journal of the Mass Spectrometry Society of Japan (JMS) in 1992. It contains many excellent review papers and reports of primary research, and is available worldwide, but is intended largely for the home market because many papers are published in the Japanese language. However, the non-Japanese scientist may still extract much useful information because the titles, author abstracts, figures and tables, references, and some technical data in the body of the text are in English.

The International Journal of Mass Spectrometry and Ion Physics (Elsevier Science, Amsterdam, The Netherlands) was the second MS journal to be published, being launched in 1968. It was retitled International Journal of Mass Spectrometry and Ion Processes in 1993, then International Journal of Mass Spectrometry (IJMS) in 1998. It has always aimed to publish papers on the fundamental aspects of MS and ion processes, including new instrumentation and practical applications. This journal also produces regular special issues, some of the later ones covering MALDI MS, electrospray ionization and ion spectroscopy. Other special issues are regularly produced in honor of eminent scientists in the field.

Also first published in 1968 was Organic Mass Spectrometry (OMS, Heyden). Its sister publication Biomedical Mass Spectrometry (BMS, Heyden, London, UK) was launched in 1974 and both journals were acquired by John Wiley & Sons in 1982. BMS underwent two name changes to Biomedical and Environmental Mass Spectrometry (1985), then Biological Mass Spectrometry (1990), before OMS and BMS were merged in 1995 to form the Journal of Mass Spectrometry (JMS), which is published under the Wiley Interscience imprint. The main reason for the merger was the convergence of the content of articles in both journals, with the movement towards biological MS in the community, and the fall in the number of pure organic MS studies, so that the journals were beginning to appear similar in any case. The current scope of the journal is wide, encompassing all aspects of MS. As well as regular articles and accelerated communications, it includes “Perspectives” and “Tutorial” articles. Each issue also contains a current awareness database that lists citations to papers on MS that have appeared recently in the chemical literature.

As a direct response to criticisms from authors about the delay times from submission of articles to publication, a new journal was published in 1987: Rapid Communications in Mass Spectrometry (RCM, Wiley Interscience). Contributions may be submitted to the journal by the normal method, whereby the Editor will send them to independent referees for assessment. Alternatively, the novel concept of sponsorship referees may be employed. Here, the authors themselves arrange for an independent referee or sponsor from another institution to act as sole referee for the paper, which is then submitted to the journal. Papers approved by referees or sponsors are generally accepted within 1–2 days and published within 4–5 weeks. The publishers also emphasize that “rapid” does not necessarily mean brief: there is no formal limit on paper length. The quick turnaround of papers has proved extremely popular with authors, as reflected in the number of issues per annual volume. This has increased from the original 12 issues to 24 in 1999. The journal publishes papers on all aspects of gas-phase ions and the associated scientific disciplines. It also publishes occasional issues that have groups of papers from a single laboratory, to illustrate the contribution that that particular organization has made to the development of MS.

In 1990, the American Society for Mass Spectrometry (ASMS) launched its official publication Journal of the American Society for Mass Spectrometry (JASMS) in conjunction with Elsevier Science. This journal also claims rapid publication of articles, with an average time following acceptance of 4 months for full papers and 2 months for communications. JASMS publishes
comprehensive research papers on all aspects of MS. The publication schedule has increased from 6 to 12 issues per annum, again reflecting both the popularity of the journal and the growth of MS. JASMS is available on subscription as with regular journals but is also supplied free to all members of the ASMS.

The most recent new journal devoted to MS was launched in 1995 when IM Publications launched EMS. To quote Allan Maccoll, the Chairman of the original Managing Board, it was felt that “there is a place for a journal of independent spirit. The unique organisation of the Journal will ensure, through its Managing Board, close contact between the Publisher and the authors and readers.” Contrary to the implication in the journal title, EMS publishes papers from worldwide sources. It aims to publish papers covering all aspects of MS, with special emphasis on the fundamental processes underlying MS: ionization, fragmentation, ion/molecule reactions and collisions, spectroscopy of gaseous ions, instrumentation and computers in MS.

A further MS journal is Mass Spectrometry Reviews (MSR, John Wiley & Sons), which is published six times a year at present. According to the co-editors Dominic Desiderio (USA) and Nico Nibbering (The Netherlands) the goals of the journal include the active solicitation of high-quality reviews from leading researchers in the field, the provision of critiques of the research published in different sub-specialities of MS, and the provision of an appropriate suppository of the research accumulated in a particular area of research in MS. Up to six reviews are published in each issue. MSR also contains a regular section entitled “Selected Reviews on Mass Spectrometric Topics”, which cites published literature references on particular areas of MS.

Apart from the core journals for MS, there exist a multitude of journals that include major papers dealing with MS developments and applications. A newcomer to MS may be surprised at the number and spread of different journals containing “useful” MS information. These are not confined to the analytical chemistry literature but are included in many different types of journals that cover chromatography, forensic chemistry, food science, biotechnology, biochemistry, toxicology, occupational hygiene, environmental chemistry, drug metabolism and pharmacokinetics, clinical chemistry and natural products chemistry.

For example, Analytical Chemistry (American Chemical Society, Washington, DC) is devoted to the broad area of analytical chemistry but contains many key papers on MS. It also contains one issue each year devoted to reviews in analytical chemistry, covering particular calendar periods. These special issues are called Fundamentals and Applications, the former appearing in even-numbered years and the latter in odd-numbered years. An article on MS appears in the Fundamentals issue. Similarly, Journal of Chromatography A and Journal of Chromatography B (Elsevier) include a large number of papers on gas chromatography/mass spectrometry (GC/MS), liquid chromatography/mass spectrometry (LC/MS) and electrophoresis coupled with MS (e.g. capillary electrophoresis/MS).

An indication of this diversity may be found by browsing the secondary journals Mass Spectrometry Bulletin (MSB, The Royal Society of Chemistry, Cambridge, UK) and LC/MS: The Applications Database (formerly LC/MS Update) (HD Science Ltd, Nottingham, UK) from 1990 onwards. This date coincides approximately with the explosion of LC/MS and soft ionization MS techniques, which expanded MS into the biological/biotechnological areas and into the bio-type journals.

MSB covers all aspects of MS in organic and analytical chemistry, physical chemistry and chemical physics, including theory, instrumentation and applications. A count of the papers in MSB selected from particular primary journals shows the level of MS content in these journals. Over the 5-year period 1994–98, 905 papers from Analytical Chemistry were selected for MSB. For the same period, 734 papers from Journal of Chromatography A and 462 from Journal of Chromatography B were included. This distribution of MS over the different subject areas is illustrated in Table 2, which shows the

numbers of papers in journals representing different disciplines over the period 1994–98, as selected for MSB. The list of publications from which papers have been selected for LC/MS: The Applications Database is reproduced in Table 3.

### 2.2 Internet Form

All of these MS journals remain popular in printed form, but now most of them are also accessible to various degrees as on-line versions via the Internet. The bibliographic details of the Elsevier journals IJMS\(^2\) and JASMS\(^3\) can be searched at the Elsevier Web site. A free public service enables nonregistered users to search the tables of contents using titles, authors or keywords, and these are the only details displayed as search results. Subscribers to the printed versions may search the full papers on-line, with a free trial period. The Internet version of JASMS also displays “fast track” articles. These are fully peer-reviewed papers that have been accepted for publication, which are posted electronically as pre-copy-edited files within 2 weeks of acceptance. They are still considered to be “in press” by the publisher until the full articles appear on the printed page.

Two further general Web-based services offered by Elsevier are ContentsDirect,\(^4\) and ContentsSearch,\(^5\) ContentsDirect is a free e-mail alerting service for their books and journals. Tables of contents are delivered to individual e-mail accounts before publication, based on the user’s predefined journal titles and their subject areas of interest for books. With ContentsSearch, the user can search the tables of contents on-line.

Internet versions of the journals JMS,\(^6\) RCM\(^7\) and MSR\(^8\) are searchable through the Wiley Web site. Non-subscribers can display the bibliography for a particular issue but do not have access to the full articles. Fully registered users can interrogate the full journal issues using simple or advanced searches, the latter permitting up to three terms to be linked (such as title, author, affiliation, author abstract) and issue and date restrictions to be applied.

The current literature databases of JMS which appear at the back of each printed issue may also be downloaded for searching within Microsoft\(^®\) Access in two forms: as the files alone or as a run-time version within Access.\(^9\) The 1997 and 1998 version are currently available.

Wiley also offers the Web-based service Wiley Chemistry.\(^10\) This offers links to several key Wiley products in chemistry. It is a different point of entry to search the book list or the Web-based journals and also provides access to news and content for Wiley journals spanning every subject area.

EMS is available as a full-text on-line journal on the IM Publications Web site.\(^11\) Subscribers to the printed journal receive free and full access to the electronic version, and there is also the option of taking out an electronic-only subscription, at a discounted price. The on-line journal is searchable with the Adobe\(^®\) Acrobat\(^®\) Reader search software, which can be downloaded and used free of charge from the Adobe\(^®\) Web site.\(^12\) The electronic journal is a direct reproduction of the printed page, including text and figures. Titles, authors and abstracts of the papers can be searched and those users with an electronic subscription can access the...
paper directly from the search results. Other users (nonsubscribers) can view the abstract only.

A further service offered by IM Publications is an alerting service for new papers in EMS. Called EMS Scan, this provides registered users with listings of titles and authors of papers in each issue of EMS when the final abstracts are made available on the Web site, generally 3 weeks before printed copies are available. Users can then visit the Web site and view these abstracts. There is no charge for this option. A sample copy may be downloaded and searched for free as a trial.

There is also a limited Web-searchable version of JMSJ. Beginning with the 1998 volume, the contents of each annual volume to date, which comprise the title, authors, corresponding address and the journal citation, can be searched using the user’s browser software. Similarly, each individual issue within a volume can be searched, from 1998 onwards, with the browser software over the same fields as above, with the addition of the author abstract. There are also plans to make a searchable keyword index available on the Web site.

Of the other non-MS journals that include papers on MS, many are also available on the Internet. Most publishers now have Internet versions or are actively working towards them. Subscribers to printed versions may be allowed free access or a specially reduced subscription to the Internet version. Some journals such as Analytical Chemistry also accept supplementary material for Web display. Apart from the usual figures and tables, this may also include animations and movie clips. The main advantage to using Internet versions is that they can be searched to locate papers of interest that can be downloaded for future reference. For retrospective searching over a series of issues, the time savings are significant. There are too many individual journal-containing Web sites to mention in this chapter and new ones are being created regularly. The reader is referred to the Web sites of the various scientific publishers for more information.

3 SECONDARY PUBLICATIONS

The previous section highlights the large number of journals that are of interest to MS practitioners, or to analysts wishing to find out about a particular MS method or an MS protocol for a particular analyte. These journals are excellent for keeping up to date, but further help is often needed to distil this information into manageable quantities, or for retrospective searching over a particular period. The on-line versions of primary journals go some way to help with this problem, although it means that the different journals must be searched separately.

Another solution is provided by secondary publications, which are generally abstracting publications. In general, these provide the titles, bibliography and abstracts of papers of interest, sometimes with added index terms. The abstracts may be direct copies of the original author abstracts, or, alternatively, are especially written for the particular abstracts publication. This type of publication is generally distributed in various formats, including printed, electronic and, more recently, on-line form. A review of the PC-based literature abstract sources for MS has recently been published.

3.1 Mass Spectrometry Publications

The products that deal solely with MS rather than chemistry as a whole are CA Selects (Chemical Abstracts Service (CAS), Columbus, OH, USA), CASurveyor® (CAS), MSB, and a series derived from the Update Series: LC/MS: The Applications Database (formerly LC/MS Update), MALDI: The Applications Database (formerly MALDI Update), Drugs: The Mass Spectrometry Applications Database and Pesticides: The Mass Spectrometry Applications Database (HD Science Limited, Nottingham, UK).

3.1.1 CA Selects

CAS, a division of the American Chemical Society, produces a large abstracts database. About 8000 titles are monitored annually, including journals, patents, symposia, conference proceedings, dissertations, technical reports and new books in chemistry. From these, approximately 700 000 documents are selected for abstracting each year and the completed abstracts are placed in one of 80 sections. CA Selects is produced by searching through all of these 80 sections for newly added papers in one of 33 specially selected subject areas, such as Mass Spectrometry. Every 2 weeks, these are gathered together and printed in booklets. Each entry includes the title, authors, the address where the work was conducted, full journal citation and full CAS abstract. The CAS abstracts are a mixture of original author abstracts and those written by CAS staff. The CAS document analysts are guided in their abstracting and indexing by the contents of the original author abstracts. If an English-language author abstract accurately and clearly summarizes the principal findings, then this abstract will probably form the basis for the CAS abstract. It may even constitute the complete CAS abstract. CAS-written abstracts are intended to provide sufficient information on the chemical content of the document abstracted to allow the reader to determine whether it is necessary to consult the original publication for complete details. The MS detail contained in the abstract can range from highly detailed to sparse,
depending on whether MS is a major or less important part of the original paper. A typical abstract is shown below.

*130: 104703a Determination of olanzapine in human plasma and serum by liquid chromatography/tandem mass spectrometry. Berna, M.; Shugert, R.; Mullen, J. (Dep. Drug Disposition, Eli Lilly and Co., Indianapolis, IN 46285 USA) J. Mass Spectrom. 1998, 33(10) 1003–1008 (Eng). John Wiley & Sons, Ltd. A liq. chromatog./tandem mass spectrometric (LC/MS/MS) assay was developed for the quant. detn. of olanzapine (LY 170053, OLZ) in human plasma and serum. Bond Elut C₂ solid-phase extn. cartridges (single cartridge or 96-well format), in conjunc-tion with a pos. pressure manifold, were used to ext. OLZ and its internal std., LY 170222, from the biol. matrix. Chromatog. resoln. of OLZ from endogenous plasma interferences and its metabolites was accomplished with a MetaChem monochrom HPLC (4.6 × 150 mm, dₕ 5 μm). Detection was carried out with a Perkin-Elmer SCIEX API III Plus mass spectrometer using pos. ion atm. pres-sure chem. ionization and multiple reaction monitoring protocol. The linear dynamic range was from 250 pg mL⁻¹ to 50 ng mL⁻¹ of human plasma/serum using a 0.5 mL aliquot. The inter-day precision (relative std. deviation) and accuracy (relative error) in plasma ranged from 6.26 to 7.66% and from −3.54 to 7.52%, resp. The intra-day precision and accuracy in serum ranged from 3.46 to 8.76% and from −8.06 to 12.46%, resp. The assay is sensitive and selective, and will be used to support both human clin. and toxicol. analyses. Furthermore, using the 96-well solid-phase extn. format, sample prepn. can be easily automated.

Even though there are 26 issues each year within each CA Selects title, they are intended as browsing publications for current awareness, because there are no indices of any sort to help with retrospective searching.

3.1.2 CA Selects Plus™

As the title implies, CA Selects Plus™ is a supplemented form of CA Selects. It is based on the same 33 subject areas, with the rapid inclusion of references from 1300 priority journals that CAS processes first, before they appear in CA itself. References to meetings, letters to the editor and other items that are not full papers and do not appear in CA are also added. Copies of original documents can be ordered from the CAS Document Detective Service.

3.1.3 CASurveyor®

This is another product derived from the full CA database, and distributed specifically on CD-ROM for Microsoft® Windows™ and Macintosh® systems. This series has 9 subject areas, called topics, one of which is entitled Mass Spectrometry and Applications. This topic includes papers on MS methodology and apparatus, experimental results obtained by spectrometric techniques, ion cyclotron resonance/MS, ion kinetic energy studies, energetics, structural studies, reaction kinetics and mechanisms, and analytical applications. The references are included from 1300 priority journals that CAS processes immediately and completely, supplemented by partial coverage of many more journals. There is complete coverage of selected core journals, such as JMS.

CASurveyor® is updated monthly on a rolling basis, each new disk giving the last 36 issues. The information can be searched, displayed, downloaded and printed. The search software will allow a particular period to be searched, such as the latest update. Searches can be conducted as a text search, in which the fields are not specified, or the search term can be specified within a particular field, such as author or journal name. The displayed records include title, authors, author affiliation, citation and abstract. Structural diagrams and CAS Registry Numbers are also included, with a link from the Registry Number to a different screen showing the relevant substance record, which may include IUPAC name, common and trade names, molecular formula and structure.

These four products are discussed together, as they are all published by the same organization, with abstracts in the same style across all publications. Originally produced as printed publications and diskette-based products (LC/MS Update; MALDI Update; GC/MS Update, Part A: Environmental and GC/MS Update, Part B: Biomedical, Clinical, Drugs) the new generation are produced on CD-ROM only. Over 250 core journals are scanned regularly, and papers are located from other journals. Each item includes the full bibliography, including all author affiliations, abstract and keywords. The abstracts differ from those in other abstracting publications in that they have a practical bias. They are especially written for these databases from the MS point of view, to highlight the mass spectrometric content of the paper and include as much of the experimental set-ups for the liquid chromatography (LC), gas chromatography (GC) and MS systems as is reported in the original. This includes the type of column, temperature or solvent program, and all published mass spectrometer conditions.
The technique-based ones. For example, a paper on the analyte-based products (Drugs and Pesticides) and analyzing these types. There is some overlap between and nonhyphenated MS methods for detecting and GC/MS, LC/MS, fast atom bombardment (FAB) MS matrix). The Drugs and Pesticides databases contain also includes laser desorption/ionization (i.e. with no soft ionization techniques. The MALDI database contains infusion and flow injection MS papers that are included in the General Index, which is divided into nine sections: Instruments, Isotopic analysis and mass measurement, Chemical analysis, Organic chemistry, Atomic and molecular processes, Surface and solid state chemistry, Thermodynamics and reaction kinetics, and Miscellaneous. Each item lists the title, authors, full journal citation and then index terms from two separate indices. The Subject index is a fixed thesaurus of about 350 terms, corresponding to common MS techniques and concepts. Topics not covered here are included in the General Index, which is divided into nine sub-sections. These indices are listed at the end of the publication, with the author index. An additional two-part term at the end of each title gives an indication of the level of MS interest in the paper, from minor to major, with full, partial or no mass spectra. A record from MSB is shown below.

3.1.5 Mass Spectrometry Bulletin

Although the MSB does not contain abstracts, it is included here because it is a secondary publication dealing solely with MS and related physical processes. The journal was first published in 1966 and is issued 12 times a year, with currently about 500 items per issue. Items are selected from over 800 primary journals as well as books, conference proceedings, reports and patents, and are placed in one of eight sections: Instruments, Isotopic analysis and mass measurement, Chemical analysis, Organic chemistry, Atomic and molecular processes, Surface and solid state chemistry, Thermodynamics and reaction kinetics, and Miscellaneous. Each item lists the title, authors, full journal citation and then index terms from two separate indices. The Subject index is a fixed thesaurus of about 350 terms, corresponding to common MS techniques and concepts. Topics not covered here are included in the General Index, which is divided into nine sub-sections. These indices are listed at the end of the publication, with the author index. An additional two-part term at the end of each title gives an indication of the level of MS interest in the paper, from minor to major, with full, partial or no mass spectra. A record from MSB is shown below.

Neg.-ion electrospray (ESP) LC/MS/MS is used to analyze the adenine nucleotide-contg. mammalian metabolites of clodronate [CAS 10596-23-3], tiludronate [CAS 89987-06-4] and etidronate [CAS 2809-21-4]. Cultured murine J774 macrophage-like cells are extd. and the metabolites dissolved in 50 mM dimethylhexylamine formate (DMHF) (pH 5.0) for anal.

LC: Rhodos 4000 pump, 20µl Rheodyne 7725 inj., 12.5 cm x 3 mm i.d. (5 µm Purospher C18e), 23°, A: 10 mM DMHF (pH 5.0 with formic acid), B: 20 mM DMHF (pH 5.0)-acetonitrile (50 : 50, v/v), 4–20% B in 10 min, to 80% B in 30 min, 0.5 ml/min.

MS: Finnigan MAT LCQ, ESP, neg. mode, –4.5 kV, capillary ~39 V and 20°, lens 55 V, N2 sheath gas, m/z 200–700, 200 ms/scan, CAD: collision energy 18%, m/z 160–700.

Mass spectra and chromatograms of the bisphosphonate adduct metabolites are presented. The adenosine phosphate metabolites of the 3 compds. are identified. Alendronate [CAS 66376-36-1] does not yield an ATP analogue.

Document type: Journal
CODEN: RCMSEF
Language: English

Keywords: Biochemical; Drugs; Electrospray technique; LC/MS; Metabolites; Pharmacology; Rat; Structure confirmation; Tamoxifen; Biological fluids

Sections: 43; General organic chemistry, Drugs and pharmacology

MSB can also be accessed on-line via ChemWeb(16) and, for the UK higher education community, via BIDS (Bath Information and Data Services)(17). In ChemWeb, the whole backfile from 1989 to date is searchable, with over 80,000 items available over all of the divisions within the printed bulletin. All the fields and indices from the printed version can be searched, either globally or over selected fields or combinations of fields. Searches may also be limited to a particular Bulletin section. The search results are displayed as a list of titles and years of publication within MSB. Full items are viewed by selecting from this list one by one. Under the terms of the agreement with the publisher, up to 10% of one database update may be downloaded or copied, and up to 1000 records may be downloaded and held for searching within the user’s organization.

3.2 Other Publications

There are numerous other products that contain abstracts of the scientific literature for various specialist markets, such as medicine, agriculture and physics. Many of these products contain some references that will be of interest to mass spectrometrists, but, for this article, dealing with the MS literature, only those products that are more specific towards MS are considered.

3.2.1 Analytical Abstracts

Although Analytical Abstracts (AA, The Royal Society of Chemistry, Cambridge, UK) is not specific to MS, it is the only other major product that produces abstracts specifically in analytical chemistry. The printed journal was established in 1954 and provides comprehensive coverage of new techniques and applications in all branches of analytical chemistry. Over 230 core journals are scanned for AA and papers from about 3000 different journals have been included. AA is updated monthly, with the addition of about 1200 items. There is a section on MS, which is generally fairly small, with most papers that include MS appearing in other sections such as Clinical and biochemical analysis, Pharmaceutical analysis and Environmental, agriculture and food. Each item contains the full bibliographic details, including the address of the corresponding (or first) author and the abstract. The abstracts concentrate on the analytical part of the original paper, even if this is not a major part of the work. The procedure is outlined and the apparatus described briefly. Analytical data such as recoveries, detection limits and coefficients of variation are included. Much detail is given on the chromatogram column and operating conditions in GC/MS and LC/MS systems, but very little information is provided on the mass spectrometer set-up. A typical abstract from AA is reproduced below.

*TI: Electrospray ionization mass spectrometry for the study of non-covalent complexes: an emerging technology.
AU: Pramanik, -BN; Bartner, -PL; Mirza, -UA; Liu, -Y-H; Ganguly, -AK
AD: Schering-Plough Res. Inst., Kenilworth, NJ 07033, USA
CP: USA
IS: 1076-5174
CO: JMSPFJ
PY: 1998
LA: English
PT: Journal
AB: A tutorial review is presented, of the utility of electrospray ionization MS for the determination of the molecular masses of non-covalent complexes with molecular masses in the range 19 000–34 000 Da. Typical examples are presented from work carried out by the authors which cover a full range of non-covalent interactions from weak to relatively strong binding energies, and these include a protein-ligand, inhibitor-protein-ligand, protein-protein and protein-metal complex interactions. The molecular masses of the complexes were determined with a mass accuracy of better than 0.01%, which is far superior to traditional methods based on SDS PAGE and GPC. The key to success in such studies depends on an understanding and manipulation of electrospray ionization source parameters and sample solution conditions. The following were found to be particularly important: (i) the orifice potential, which should be sufficient to promote ionization without dissociation of the complex; (ii) the acidity of the complex; and (iii) the use of an organic co-solvent is strictly prohibited since the interior pocket of the protein would be disrupted resulting in denaturation. The usefulness of the technique for biological problems leading to the discovery of new therapeutics and the rapid screening of potential drug candidates is also illustrated.

(33 references).

IA: complexes.-A: study of non-covalent, by electrospray MS, tutorial review

The printed version has one index, the Subject index, that is prepared with a controlled vocabulary in order to facilitate searching. Within this index, there are three categories of index term: analyte, matrix and concept.

AA is also available on CD-ROM, using the SilverPlatter Information Retrieval System (SPIRS) software in DOS, Windows® and Macintosh® formats and can be searched on the Internet, also using SPIRS. The database is covered from 1980 onwards, with quarterly updates adding about 3600 items each time. The total size is over 235,000 records. Only items from 1984 onwards contain abstracts. Those from 1980 to 1983 contain titles, bibliographic detail and index entries. In this case, the three categories of Subject index term can be separately searched. There is a basic index comprising words from nearly all the fields, which can be used to locate techniques or chemicals. Otherwise the separate fields can be specified, to locate, for example, a specific compound as analyte (analyte index) or a technique (in the concept index). In retrieved items, the search term is highlighted. Further search terms can be selected from displayed records to refine the search. Records may be sorted for viewing, printing or downloading. Searches can be saved for a later session and the saved search run on a later CD-ROM update. In the WebSPIRS version, AA can be accessed over the Internet. Customizable user interfaces can be created by the user, search screens can be tailored and there are simple and advanced search options. The software enables cross-database searching to be implemented and searches can be set to run automatically at timed intervals or when a new update is added.

AA is also available via ChemWeb® and several on-line hosts, including Dialog, DataStar (Dialog and DataStar, Dialog Corporation, Mountain View, CA, USA), Orbit (Questel Orbit, Nanterre, France), and STN (Columbus, OH, USA).

### 3.2.2 Chromatography Abstracts

A further abstracting journal in the analytical chemistry area is Chromatography Abstracts (The Royal Society of Chemistry), produced in printed form only. This was originally published by the Chromatographic Society and is now in its 42nd annual volume. It covers chromatography and separation science, divided into five sections: General and Miscellaneous Techniques, GC, LC, Electrophoresis and Thin-layer chromatography. The MS papers can occur in any of the five sections. The abstracts are specially written in a similar manner to those of AA, concentrating on the analytical and chromatographic details of the original publication, such as sample sizes, column type and column conditions. Although the mass spectrometric experimental details are not highlighted, more detail is sometimes given than in the original author abstract. A typical record is shown below.

```

3-Chloro-p-toluidine hydrochloride (I) and its deuterated analogue (internal standard: IS) were extracted from spiked pigeon breast or gastrointestinal tissue with 2N-NaOH saturated with NaCl and back-extracted with propan-2-ol and hexane, then isolated on a silica (1g) SPE column. Analytes I and IS were eluted with 2ml n-butylic acetate, subsequently diluted to 5ml. Portions were analysed by GC on a fused-silica column (30m × 0.25mm i.d.) coated with DB-1 (0.25µm) operated with temperature programming from 90°C (held for 0.25 min) to 300°C at 35°C/min with He as carrier gas (1ml/min) and EIMS detection operated in selected-ion monitoring mode at m/z 106, 140 and 141 and 112, 147 and 149, respectively, for I and IS. The calibration graph was linear from 0.025–2µg/ml of I, with a detection limit of 0.03µg/g in both tissues. Recoveries of I from fortified tissues were 56.4–92.4%, whereas surrogate corrected recoveries were 95–101%.
```

The Subject index leads to some papers via the index term “mass spectrometry”, but many other papers are found under index terms for the analyte or group of analytes, so much browsing is required to locate all of the MS articles.

#### 3.2.3 Current Contents

Current Contents (CC) is a bibliographic database published by the Institute for Scientific Information, Philadelphia, PA, USA. It is a more general product, covering the published research literature, using over 7000 journals and 2000 books for inclusion in one of seven editions. The three editions that contain material of interest to mass spectrometrists are Physical, Chemical and Earth Sciences, Life Sciences and Clinical Medicine, covering 957, 1374 and 1045 publications, respectively.

The items include full bibliography, keywords and, except for the printed edition, author abstracts. No special efforts are made outside of the normal keyword creation to emphasize the MS content of the original publication. Five distribution formats are available for CC: printed, diskette, via File Transfer Protocol (FTP), CD-ROM and on the World Wide Web.

The diskette version is supplied in Windows® or Macintosh® versions and the inclusion of abstracts is optional. The FTP option allows delivery of the same data and functionality as the diskette, the main advantage being speed of delivery. Multi-issue searching of the diskette and FTP versions is possible, with nine different search options, including journal, title, author and keyword. The search results may be printed and downloaded. The tables of contents of journals may also be browsed page by page.

CC on CD-ROM is issued weekly on a 52-week rolling basis, with an annual CD-ROM at the end of each year. This version is in Windows® and DOS formats, and uses the Ovid® software (Ovid Technologies, New York) for searching. There are 18 discrete search fields. The Web version, Current Contents Connect™, also allows access to a 1-year rolling file and has multi-query searching. All data, including abstracts, can be searched using simple search strategies of personalized search profiles. The records may be exported into other data management software. A novel aspect of the Web version is the inclusion of Web links to facilitate communication with the corresponding authors or publishers.

All five CC formats have facilities for ordering copies of the original document. Two complementary products from ISI are the CC Reference Edition and CC Proceedings. The former is a quarterly CD-ROM that accumulates to an annual archive disc and is useful in conjunction with the diskette and printed versions. CC Proceedings is a monthly diskette product containing complete information on conferences, symposia and workshops in the two editions: Engineering and Physical Sciences and Biomedical, Biological and Agricultural Sciences.

4 MISCELLANEOUS LITERATURE SOURCES

Other printed sources of MS information include trade journals or magazines that are free to individual subscribers who fulfill the qualifying criteria (which are not usually very rigorous). There are none covering MS alone, but several deal with spectroscopy in general, including Spectroscopy (Advanstar Communications, Cleveland, OH, USA), Spectroscopy Europe (Wiley-VCH, Weinheim, Germany, IM Publications, Chichester, UK) and International Spectroscopy Laboratory (a subset of International Laboratory, International Scientific Communication, Shelton, CT, USA). Other publications of this type that are directed towards chromatographers, such as CAST (Chromatography and Separation Technology, RoseWard Publishing, Guildford, UK) and the more general laboratory publication, such as LabAnalytica International (Globetech Publishing, Wilton, CT, USA), also occasionally contain items related to MS, although some are written as promotions of MS equipment by representatives of instrument manufacturers.

Many conference proceedings are also published separately, but circulation may be limited to the conference delegates. In these cases, it is arguable whether or not the proceedings should be considered as published. In addition, the contents often consist of posters or presented papers that have not been refereed before publication. The quality of some entries may be questionable and much of the work is still in progress. Some, but by no means all, of these conference proceedings may be published later as full articles in a regular journal (or as a special journal issue) or as a book, when the work is more complete and the submissions have been refereed. Only then do some scientists accept them as valid, trustworthy publications.

One notable exception to the perceived value of nonrefereed conference proceedings is the extended abstracts from the ASMS annual meeting, published in book form up to 1998 and on a CD-ROM from 1999. Despite the lack of refereeing, it is evident from citations in other published MS papers that there is more confidence attached to these submissions and they are often used to establish scientific credit.

A further source of MS information is the application notes published by the mass spectrometer manufacturer. These will contain much technical information, generally on novel aspects or applications of the instrumentation, and are usually available by ordering from the appropriate Web site.

5 INTERNET RESOURCES

The Internet is a vast resource available to scientists, and reference to its uses in other aspects of MS and analytical chemistry will be made in other parts of this encyclopedia. For mass spectrometrists, one of the main uses is to identify the many different sources of chemical literature that may be available in printed, diskette, CD-ROM, online and Internet-based formats. These may be produced by government organizations, commercial organizations and academia, and no attempt is made here to locate and identify them all. In general, these sources include the bibliography from the original citation and some also
contain chemical structures and author abstracts. They are intended for more general markets, such as chemistry or medicine, but remain useful for directing the user within that area to more specific papers on MS and related subjects.

Some of the initial problems encountered in using the Internet involved filtering the sites to find the useful ones, but these have been partly eradicated. However, a general search of “mass spectrometry” will give a large, almost unmanageable number of hits, with many useful ones far down the list. To alleviate this problem, some Web sites have been specifically designed to provide links to sites of most interest to mass spectrometrists. The first and currently one of the best of these was set up and maintained at Emory University by Kermit Murray, and is now operated by John Wiley & Sons under the title Base Peak, with Murray as Editor. A full explanation of the original purpose, design and intended use of this site has been published. It is organized under various headings, all listing live links to other sites: organizations (national societies and associations), journals, meetings, local MS discussion groups, listservers, Usenet groups, information/archives, education, employment and non-English language resources. There is also a section set up so that the user can search the World Wide Web by selecting one of the many popular Web search engines. Wiley have also added links to their own Web site to the journals and books pages.

Many of the sites, such as those of the national MS societies and groups, also have links to other MS resources, including publishers, so that an intricate and valuable subset of the World Wide Web devoted to MS is building up. Many sites now exist simply to provide links to other sites, by collecting together the addresses of journals that are published on the World Wide Web. Some subscription agencies, such as Ebsco On-line, Blackwell’s Electronic Journal Navigator, Dawson/Faxon Information Quest and SwetsNet, provide links to the electronic journals on the Internet. Other Web sites, like ChemPort, offer additional services, such as links from search results in several reference databases, to the corresponding full electronic text at publishers’ sites. Some sites, many of which are maintained by particular academic departments, exist mainly to provide a service to their students, by collecting together information on sites of interest. Many of these sites are not restricted to the student but may also be accessed from outside the organization.

The ASMS is also making available the preliminary abstracts of its annual conference on the Web, at the ASMS Web site. The abstracts may be searched online. Additionally, the required viewer program and the abstracts from any or all of the conference sessions can be downloaded for the PC or the Macintosh and searched free of charge. The extended abstracts are distributed on CD-ROM.

A more specialized, but nevertheless useful, Internet resource comprises part of the Web site at www.lcms.com. Listed here are the appendices from the book A Global View of LC/MS (see entry under the book section). These provide sources for LC/MS information under various headings and are kept up to date, so providing dynamic appendices to the book. The literature resources include books, selected reviews, on-line services, journals, training and education.

The first Internet-only journal to be published, The Internet Journal of Chemistry (IJC), was published in 1998. IJC is a purely electronic journal, with all submissions and publications done over the Internet. The statement of purpose includes the intention to use the special features of the Internet to represent images in three dimensions and in color, to publish dynamic processes as movies, to keep costs to a minimum and to give the subscriber the ability to customize journal output. It is probably only a matter of time before more journals, including MS journals, are published this way. The representation of peptide and protein processes in MS, for example, would benefit greatly by the use of three-dimensional imaging and color to represent conformational changes and fragmentations. The journal Analytical Chemistry now accepts supplementary material for display on the Internet and this concept is under consideration by the publishers of the main MS journals.

6 BOOKS

Books on all aspects of MS are included in this section, with the general guideline that they are included if published from 1990 onwards. This rule of thumb is relaxed for older books which are still relevant today, such as books on the principles of MS, rather than, for example, books on MS in the biosciences, in which there have been huge advances during the 1990s. This article attempts no critical review of any of the books, but rather an indication of the content of each. For details of new books published after March 1999, the reader is referred to the Web-based catalogs of the various publishers, and also to the Web sites at www.amazon.com and www.bol.com which contain details of several million published books on all subjects.

The books listed here are segregated into three broad sections: Data compilations, Basic MS and teaching texts, and Applications. Within each section the books are sorted chronologically.
6.1 Mass Spectrometry Data Compilations

**Mass Spectra and GC Data of Steroids, Androgens and Estrogens**

In the SpecBook Series by Chemical Concepts, this collection contains almost 2500 newly measured mass spectra of androgens and estrogens and is the most comprehensive collection of mass spectral data currently available. Each spectrum is accompanied by its structure, systematic and trivial names, retention index, molecular formula and mass, CAS Registry Number and sample source.

**Mass Spectral and GC Data of Drugs, Poisons, Pesticides, Pollutants and their Metabolites, Parts I–IV, 2nd edition**

K. Pfleger, H.H. Maurer, A. Weber

This expanded second edition compiles GC data and the complete mass spectra of 6000 toxic compounds and their metabolites, with the addition of over 1500 new mass spectra in the newly released Volume IV. Tables of approximately 7500 potential poisons, giving empirical formulae, molecular weights, CAS Registry Numbers and pharmacological/toxicological categories make it possible to attempt identification of compounds whose spectra have not yet been recorded. Relevant search criteria (e.g. name, category, molecular weight) can be searched in separate lists. All spectra were measured in the authors’ laboratory by a standardized procedure.

**Instrumental Data for Drug Analysis, Volumes I–VII**

In the Forensic and Police Science Series, this self-contained set contains information on over 1600 drugs, metabolites, drug-related compounds and pesticides. Data include chemical title, molecular formula and weight, synonyms and trade names, structures, Fourier transform infrared, nuclear magnetic resonance, ultraviolet, GC data and detailed mass spectral data. Volume VII contains the cumulative indices.

**Identification of Essential Oil Components by Gas Chromatography/Mass Spectroscopy**

R.P. Adams

This updated book contains the mass spectra and retention times of over 1200 of the most common compounds in essential oils derived from plants. The compounds are listed in order of their elution on a DB-5 column and Kovat’s indices are included. The book is available separately or in combination with a diskette-based library for use with mass spectrometer data systems. The instrument formats available are Finnigan GCQ/Magnum & ITS 40 (.LBR), Finnigan ICIS (.LIB), Finnigan ion trap (.LIB), Finnigan Incos (.LS), Fisons/VG Mass Lab (.IDB), Fisons/VG Lab Base (.IDB), HP JCAMP & Unix (.HPJ), HP Chemstation (.L), net CDG (.CDF), Palisade BenchTop/PBM (.SPC), Shimadzu QP5000 (.NAM), Teknivent Vector/2 (.SPC), Varian Saturn (.LBR) and Waters Millennium (.SPC).

**The Eight Peak Index of Mass Spectra, 4th edition**

This printed index of mass spectral data contains the eight most abundant $m/z$ and intensities of over 81 000 mass spectra covering over 65 000 compounds. Molecular formula and weight, compound name, parent peak intensity and CAS Registry Number are also present. The complete data are sorted in three different ways, laid out in tables to allow easy identification of unknown compounds by (i) molecular weight subindexed on formula, (ii) molecular weight subindexed on $m/z$ values, and (iii) $m/z$ of the two most abundant ions.

**GC/MS of the Gibberellins and Related Compounds: Methodology and a Library of Spectra**

P. Gaskin, J. MacMillan (eds.)

This book contains 951 electron impact mass spectra of gibberellins as trimethylsilyl, methyl ester-trimethylsilyl ether and trimethylsilyl ether-trimethylsilyl ester derivatives, to provide GC/MS reference data. Also included are chapters on methodology and on procedures for editing GC/MS data. A companion diskette version containing the line diagram mass spectra of all compounds is also available.

**Important Peak Index of the Registry of Mass Spectral Data**

F.W. McLafferty, D.B. Stauffer (eds.)

This is a derivative of the Wiley/NBS Registry of Mass Spectral Data (1989) and presents the same
information in different orders for different points of entry to the data. It selects from each spectrum only those peaks that are diagnostic for that compound. There are 136,141 different mass spectra of 115,917 compounds.

Wiley/NBS Registry of Mass Spectral Data
F.W. McLafferty, D.B. Stauffer (eds.)
This collection covers spectra for 112,272 compounds with structures for 89,903 compounds. The spectra are selected from 150,000 different spectra. The Registry features vertical column formatting for easy cross-comparison of mass spectra. Data are contributed from laboratories worldwide. The electronic version of this product has continued to be expanded and now contains 392,000 mass spectra.

Analytical Artifacts, GC, MS, HPLC, TLC and PC
B.S. Middleditch
This contains information on artifacts encountered in organic analysis. Emphasis is on impurities, by-products, contaminants and other artifacts and over 1100 entries are included. Each entry contains the common name, mass spectrum, GC data, CAS name and Registry Number, synonyms and a narrative discussion. Mass spectral data are indexed in a six-peak index. There are also formula, author and subject indices. An extensive bibliography contains complete literature citations.

C.R. Pace-Asciak
This title contains line diagram mass spectra of derivatized prostaglandins and related compounds.

Electron Capture Negative Ion Mass Spectra of Environmental Contaminants and Related Compounds
R.A. Hites, E.A. Stemmler
This volume contains the electron capture negative ionization (ECNI) line diagram mass spectra of 361 compounds selected to include the major classes of environmental contaminants. Compound names, CAS Registry Numbers, molecular weights and structures are also given.

6.2 Basic Mass Spectrometry and Teaching Texts

The Bile Acids. Chemistry, Physiology and Metabolism. Vol. 4: Methods and Applications
K.D.R. Setchell, D. Kritchevsky, P.P. Nair (eds.)
One of the chapters on the MS of bile acids (Lawson and Setchell) gives 112 line diagram mass spectra of bile acid methyl ester–trimethylsilyl ether derivatives, and an appendix lists GC retention indices.

Pharmaceutical Mass Spectra
R.E. Ardrey, A.R. Allen, T.S. Bal, A.C. Moffat
This is a compilation of mass spectra of drugs, metabolites and other compounds of pharmaceutical interest. Over 1100 full spectra with ion lists are arranged in alphabetical order of compound name. Derivatives and thermal degradation products are indexed under the parent compound. It includes a molecular weight index, an eight peak index and an alphabetical index of compound names.

can also serve as a self-help book. An overview of the theory and instrumentation is provided. Real-life problems are used as examples for the reader to solve, with answers and complete explanations at the end of the book.

Mass Spectrometry, 2nd edition

J. Barker

This is the latest edition in the Analytical Chemistry by Open Learning (ACOL) Series. It provides an introduction to MS suitable for self-learning. The practical approach combines theoretical and operational aspects. Ion formation, instrumentation, interpretation of simple spectra and recent interfaces (electrospray, continuous-flow) are included.

A Beginner’s Guide to Mass Spectral Interpretation

T.A. Lee

This book is dedicated to the interpretation of mass spectra and excludes information on hardware and experimental conditions, which may be of limited use in the interpretation. It is aimed at under- and postgraduate level. Each chapter concentrates on a different class of compound, such as hydrocarbons, halocarbons, alcohols, ethers and phenols, aldehydes and ketones, N-containing compounds, thiols and thio ethers and heterocyclic compounds.

GC/MS. A Practical User’s Guide

M.C. McMaster, C. McMaster

This guide provides practical information on using, maintaining and troubleshooting a GC/MS system. It progresses through the stages of setting up a system, and performing an analysis, with practical tips. A basic coverage of the theory is provided to illustrate operational variables and their control.

Liquid Chromatography/Mass Spectrometry. 2nd edition, Revised and Expanded

W. Niessen

This revision, part of the Chromatographic Science Series (no. 79), provides an updated and comprehensive account of the latest developments, principles and applications of LC/MS and related techniques. It covers all interfaces currently used, especially atmospheric pressure chemical ionization and electrospray, and includes discussions on the optimization of experimental and ionization conditions. There is an expanded applications section covering environmental, pharmaceutical, natural products/endogenous compounds, biochemical and miscellaneous applications.

A Global View of LC/MS. How to Solve Your Most Challenging Analytical Problems

R. Willoughby, E. Sheehan, S. Mitrovich

Written in the style of a “how-to” book, this is a practical guide to learning about, acquiring equipment and making the correct choices in LC/MS. The four sections cover: Is LC/MS right for you?; Acquiring LC/MS capabilities; Solving problems with LC/MS; and Appendices (Sources for LC/MS information, Practical information for LC/MS, Interfaces – how do they work? Mass analyzers – how do they work? Pioneers in LC/MS). Structural approaches are given for interpretation, target analysis, quantification and method development.

Ionization Methods in Organic Mass Spectrometry

A.E. Ashcroft

This book concentrates on instrumental operation and gives step-by-step instructions on how to set up mass spectrometers using various ionization types. Atmospheric pressure chemical ionization, electrospray, electron ionization, chemical ionization, FAB, fast ion bombardment ionization (including continuous-flow), field desorption, field ionization, thermospray, and MALDI are included.

Electrospray Ionization Mass Spectrometry: Fundamentals, Instrumentation, and Applications

R.B. Cole (ed.)

This is the only book currently available that deals solely with electrospray ionization. It presents a wide view of the current knowledge of the basic aspects of electrospray ionization MS. It is divided into four main sections, covering fundamental and mechanistic aspects of the electrospray process, coupling electrospray to various mass analyzers, interfacing electrospray to separation techniques, and applications to biochemistry.

Spectral Interpretation of Organic Compounds

E. Pretsch, J.-T. Clerc

In the series Spectroscopic Techniques: An Interactive Course, this is a book/CD-ROM combined tutorial introducing the interpretation of 13C- and 1H-nuclear magnetic resonance, infrared, ultraviolet/visible spectroscopy and MS data. It is a hands-on tutorial based on the SpecTool product.

Tandem Techniques
R.P.W. Scott
In the Separation Science Series, the functions and uses of instruments combining separation and identification techniques for analyzing mixtures are described. The interfaces are described in detail and comparative performance data is presented. The techniques include GC/MS and LC/MS. 1997, John Wiley, ISBN 0-471-96760-2

R.M. Silverstein, F.X. Webster
This is a self-teaching book on the identification of organic compounds from their mass, infrared and nuclear magnetic resonance spectra. It follows a problem-solving approach, with a large set of real data problems and an extensive set of reference charts and tables. 1997, John Wiley, ISBN 0-471-13457-0

Introduction to Mass Spectrometry, 3rd edition
J.T. Watson
This completely revised and updated edition provides a guide to the concept of MS and demonstrates its potential and limitations. Using real-life examples, the book presents 18 realistic cases of qualitative and quantitative applications of MS. Systematic descriptions of the various types of mass analyzers and other mass spectrometer components, and strategies for interpretation of data, are included. This edition has eight new chapters, including six devoted to various types of ionization, such as electrospray, MALDI and inductively coupled plasma. 1997, Raven Press, ISBN 0-39751-688-6

Mass Spectrometry and its Applications
E. De Hoffmann, J. Charette, V. Stroobant
This is an introductory book covering the basics of MS. It covers many important modern techniques, such as electrospray ionization and MALDI, as well as modern instrumentaton. It includes applications of MS to biological molecules, analysis of complex mixtures, and analysis of samples that require derivatization, chromatography and/or tandem analysis. 1996, John Wiley, ISBN 0-471-96696-7 (hardcover), ISBN 0-471-96697-5 (paperback)

Mass Spectrometry for Chemists and Biochemists, 2nd edition
R.A.W. Johnstone, M.E. Rose
This is a teaching text aimed at undergraduate and postgraduate levels, requiring no previous knowledge of MS and adopting an instructional approach. This edition includes new methods and applications that have developed in the past 10 years. Methods combining MS with newer separation techniques and analysis of polar and large-mass compounds such as proteins are discussed. 1996, Cambridge University Press, ISBN 0-521-41466-0 (hardback), ISBN 0-521-42497-6 (paperback)

Gas Chromatography and Mass Spectrometry. A Practical Guide
F.G. Kitson, B.S. Larsen, C.N. McEwen
This book covers the GC separation conditions for many compound types provided as derivatized and underivatized compounds. There is extensive correlation of ion masses and neutral losses with possible structures, and examples of spectra are provided. Also included is basic information on instrumentation, ionization methods, quantification, operating tips and derivatization procedures. The various appendices include troubleshooting tips for GC and MS. 1996, Academic Press, ISBN 0-12-833885-3

Quadrupole Mass Spectrometry and its Applications
P.J. Dawson
This book was originally published in 1976 by Elsevier and is reprinted as an American Vacuum Society Classic. It provides a broad study of the development and use of quadrupoles and the actions of radiofrequency fields, from basic operating principles to their use in mass filters, monopoles, ion traps and time-of-flight mass spectrometers. 1995, American Institute of Physics, ISBN 1-56396-455-4

Ion Traps
P.K. Ghosh
In the International Series of Monographs on Physics, this is the first book to present the principles of operation of both Paul and Penning ion traps. It examines confinement in both traps, including ion cooling. Applications of the traps in atomic physics and in frequency standards, collision studies and the use of the Paul trap in analytical chemistry are covered. 1995, Clarendon Press, ISBN 0-19-853995-9

R.E. March, J.F.J. Todd (eds.)
This is an account of the development and theory of the quadrupole ion trap, its utilization as an ion storage device, a reactor for ion/molecule reactions and as a mass spectrometer. Four chapters cover the fundamental aspects, including theory, development, operating principles and the production of the first
commercial version. Four more chapters cover the environment within the ion trap, including collisional cooling, ion trajectory simulations, boundary excitation and ion/molecule reactions.

Practical Aspects of Ion Trap Mass Spectrometry. Volume II. Ion Trap Instrumentation
R.E. March, J.F.J. Todd (eds.)
This volume covers the research and applications of ion trap instruments, often in tandem with other instruments or components, such as external ion sources and lasers. Also covered are high-resolution MS and mass measurement accuracy, ion trap confinement of externally generated ions, including by electrospray, ion structure differentiation, lasers, and ion traps in the study of physics.

Experimental Mass Spectrometry
D.H. Russell (ed.)
This book is designed as a guide for non-specialists, providing a thorough discussion of practice in modern MS, at the time of publication. Areas include biological MS, negative ion chemistry, collision-induced dissociation in tandem/structural MS, fundamental aspects of Fourier transform/ion cyclotron resonance (FT/ICR) MS and aspects of protein structure.

J.R. Chapman
A fully updated edition, it includes time-of-flight and Fourier transform instrumentation and has an expanded LC/MS section, a new section on SFC/MS, and a new chapter on “in-solution” ionization techniques and their use in LC/MS coupling. Other chapters cover chemical ionization and ion–molecule reactions, negative ion chemical ionization, tandem MS (MS/MS) and quantitative analysis.

Spectroscopic Methods and Analyses. NMR, Mass Spectrometry, and Metalprotein Techniques
C. Jones, B. Mulloy, A.H. Thomas (eds.)
In the Methods in Molecular Biology Series (No. 17), this book gives practical information on these three research tools, such as required sample sizes and purities, advantages and limitations of the techniques, and data interpretation. The MS section includes an introduction and sections on laser desorption/ionization of bio-organic molecules, plasma desorption time-of-flight mass spectrometry (TOF MS) of peptides and proteins, FAB MS of peptides and tandem techniques.

Interpretation of Mass Spectra, 4th edition
F.W. McLafferty, F. Turecek
This is the latest edition of the classic book on mass spectral interpretation, which uses set problems throughout the text for the reader to practice and gain experience. This edition contains new chapters related to ion energetics involved in fragmentation.

Laser Ionization Mass Spectrometry
A. Vertes, R. Gijbels, F. Adams (eds.)
This book takes a comprehensive look at the new hardware and investigative possibilities of this form of analysis. It links theory with applications and provides chemists using MS with a definitive guide to laser ionization MS up to the early 1990s.

Liquid Chromatography–Mass Spectrometry: Techniques and Applications
A.L. Yergey, C.G. Edmonds, I.A.S. Lewis, M.L. Vestal
This is an older treatment of LC/MS but is still very useful as there are so few books dealing exclusively with the subject. It covers direct liquid introduction interfaces, mechanical transport devices, thermospray and particle beam interfaces. Special coverage is given to nucleic acid constituents, glucuronides, acylcarnitines, sulfates, amino acids, peptides and proteins.

Field Desorption Mass Spectrometry
L. Prokai
In the Practical Spectroscopy Series, this book covers all aspects of field desorption MS: principles, experimental techniques and methods, general practice and applications.

Mass Spectrometry/Mass Spectrometry: Techniques and Applications of Tandem Mass Spectrometry
K.L. Busch, G.L. Glish, S.A. McLuckey
The only book devoted to MS/MS, this deals with the basic concepts of the technique and reviews the various types of instrumentation used. The different types of reaction involved in MS/MS are also considered, along with MS/MS spectra interpretation. Applications
in environmental chemistry, natural products chemistry, industrial products, foods and flavours, forensic chemistry, petroleum chemistry and the pharmaceutical industry are covered.

Quadrupole Storage Mass Spectrometry
R.E. March, R. Hughes

This monograph provides an extensive discussion of the operation of the ion trap detector and its application in MS. It surveys results obtained with the ion trap detector in gaseous ion spectrometry and physics. Applications of ion trap MS to toxicological studies, metabolism studies, environmental problems, water analysis and forensic science are covered.

A.G. Marshall, F.R. Verdun

A unified treatment of the three most popular types of Fourier transform spectroscopy is presented, with uniform notation. All mathematics is self-contained and requires only a simple knowledge of calculus. Following the general treatments, one chapter is devoted to FT/ICR MS.

Basic Gas Chromatography/Mass Spectrometry. Principles and Techniques
F.W. Karasek, R.E. Clement

This book covers the basic principles of GC and MS alone and in a GC/MS system. The data generated and their use are covered in detail, with extended coverage of the use of the computer and mass spectral search techniques. Qualitative and quantitative aspects are covered. GC/MS-computer applications are presented.

Techniques of Combined Gas Chromatography Mass Spectrometry: Applications in Organic Analysis
W.H. McFadden

A comprehensive book on the state-of-the-art of GC/MS, this book still contains much relevant material today.

Tandem Mass Spectrometry
F.W. McLafferty (ed.)

This book contains a collection of topics dealing with MS/MS as practiced in the early 1980s.

Quantitative Mass Spectrometry
B.J. Millard

Even though this book is over 20 years old, it is the only book devoted to quantitative MS and contains information that is still relevant today.

Mass Spectrometry. Organic Chemical Applications
K. Biemann

This is Volume 1 of the ASMS series Classic Works in Mass Spectrometry, which consists of books of historical and practical interest that are out of print. Chapters on instrumentation, sample handling and operating techniques, interpretation of mass spectra, and isotopically labelled compounds are followed by several chapters on the mass spectra of different compound classes, such as fatty acids and alkaloids.

Mass Spectrometry and its Application to Organic Chemistry
J. Beynon

This is the second book in the ASMS series Classic Works in Mass Spectrometry.

1960, Elsevier, no ISBN, republished 1999 by the ASMS

6.3 Applications of Mass Spectrometry

GC/MS in Clinical Chemistry
P. Gerhards, U. Bons, J. Sawazki, J. Szigan, A. Wertmann

The basic principles of GC/MS are explained, with reference to applications in industrial medicine and drug analysis. Sample preparation methods and quality assurance are also covered. Drug information on epidemiology and pharmacology is presented to aid in drug screening studies.

New Methods for the Study of Biomolecular Complexes
W. Ens, K.G. Standing, I.V. Chernushевич (eds.)

This volume is in the NATO Science Series: C Mathematical and Physical Sciences (Vol. 510) and covers the proceedings of the NATO Advanced Study Institute Workshop held in 1996 in Alberta, Canada, on the study and characterization of noncovalent biomolecular complexes by electrospray and MALDI MS. Mass spectra of large complexes (several hundred kilodaltons) have been obtained on sector, quadrupole, time-of-flight and ion cyclotron resonance instruments. The use of other techniques in combination with MS for studying supramolecular complexes is also discussed.

**Advances in Mass Spectrometry, Vol. 14**  
E.J. Karjalainen, A.E. Hesso, J.E. Jalonen, U.P. Karjalainen (eds.)  
This is the latest volume in the series reporting the proceedings of the International MS Conferences, this one being held in Tampere, Finland, in 1997. The articles are divided between a book and a CD-ROM. The book contains 33 papers. The CD-ROM has 300 additional papers, a copy of the book for easy searching, the conference abstract book and a QuickTime film recording of the closing lecture by R.G. Cooks.  

**Mass Spectrometry of Biological Materials, 2nd edition, Revised and Expanded**  
B.S. Larsen, C.N. McEwen (eds.)  
This edition has been completely rewritten and enlarged. It reviews ionization methods and instrumentation, introduces new technology, covers the isolation and characterization of very low levels of biological molecules and supplies in-depth coverage of screening protein databases using mass spectrometric data.  

**Inductively Coupled Plasma Mass Spectrometry. From A to Z**  
A. Montaser (ed.)  
This book covers new instrumentation, theory and applications of inductively coupled plasma MS. Fundamental applications, sample introduction, radiofrequency generators, and comparisons with other plasma mass spectrometric systems are covered.  

**Current Practice in Liquid Chromatography/Mass Spectrometry**  
W.M.A. Niessen, R.D. Voyksner (eds.)  
A spin-off from the *Journal of Chromatography A*, Volume 794, this book contains invited papers on modern aspects of LC/MS, all of which have been peer-reviewed in the normal manner for journals. The sections cover pharmaceutical/biomedical applications, environmental applications, natural products analysis, electromigration techniques and fundamentals/instrumentation.  

**Trace Determination of Pesticides and their Degradation Products in Water**  
D. Barcelo, M.-C. Hennion (eds.)  
In the Techniques and Instrumentation in Analytical Chemistry Series (Vol. 19), this is a critical compilation of analytical methods for monitoring pesticides and their degradation products in water. The section on general chromatographic methods includes electrophoresis, GC/MS and LC/MS techniques.  

**Secondary Ion Mass Spectrometry. SIMS X**  
A. Benninghoven, B. Hagenhoff, H.W. Werner (eds.)  
This is the latest book in a series, containing the proceedings of the 10th International Conference on Secondary Ion MS (1995), providing an overview of current research. Over 200 papers are included.  

**Selected Topics in Mass Spectrometry in the Biomolecular Sciences**  
R.M. Caprioli, A. Malorni, G. Sindona (eds.)  
This volume is in the NATO Science Series: C Mathematical and Physical Sciences (Vol. 504) and covers the Proceedings of the NATO Advanced Study Institute held in Altavilla-Milicia, Italy in 1996. Many fundamental aspects of MS are presented, including the principles and applications of electrospray, ion spray, MALDI, GC/MS interfaces and tools for quantitative analysis. The major part of the book deals with peptides, proteins, oligonucleotides, DNA adducts, polysaccharides, lipids, and plant metabolites.  

**Time-of-Flight Mass Spectrometry. Instrumentation and Application in Biological Research**  
R.J. Cotter  
The basic principles of TOF MS are presented, with a strong emphasis on biological research. Techniques such as orthogonal extraction, post-source decay and delayed extraction and the various compatible ionization techniques are covered. Applications to peptides, proteins, oligonucleotides and human genome sequencing are discussed.  

**Stable Isotopes**  
H. Griffiths, D. Robinson, P. Van Gardingen  
The growing range of applications of stable isotopes for probing biological and geochemical cycles is reviewed in an interdisciplinary approach.  

**Plasma Source Mass Spectrometry. Developments and Applications**  
S.D. Tanner, J.G. Holland (eds.)  
A current perspective on elemental analysis by plasma source MS is presented. The contents include elemental
analysis in liquids and solids, on-line separation, ion optics, instrumental developments, analytical applications and the quantification of radionuclides.

Handbook of Drug Analysis Applications in Forensic and Clinical Laboratories
R.H. Liu, D.E. Gadzala

This book covers preliminary test and chromatographic methods in forensic drug testing, reviews identification methods such as molecular spectrophotometry, nuclear magnetic resonance (NMR) and MS, and discusses the fundamental relationship between instrumentation and drug analysis. It also evaluates the characteristics and pretreatment approaches for common sample categories and provides proven laboratory procedures for the analysis of commonly abused drugs.

Techniques in Protein Chemistry
R.H. Angeletti (ed. 1993)

This benchtop reference guide for protein chemists features up-to-date advances in protein methodologies. Most volumes contain sections on the use of MS in protein and peptide analysis.

Modern Isotope Ratio Mass Spectrometry
I.T. Platzer

This is the first book on this subject for many years and it includes a comprehensive element-by-element review of 94 elements. Applications from the fields of analytical chemistry, geochemistry, astronomy and biomedical science are included, with special reference to technical details and instrumentation.

Larger Ions. Their Vaporisation, Detection and Structural Analysis
T. Baer, C.Y. Ng, I. Powis (eds.)

In the Wiley Series in Ion Chemistry and Physics, this book covers the mass spectrometric analysis of large molecules by techniques that include Fourier transform MS and MALDI MS. Models for MALDI, the laser ejection of oligomers, and collisional activation of large molecules are studied.

Applications of LC/MS in Environmental Chemistry
D. Barcelo (ed.)

In the Journal of Chromatography library (Vol. 59), this is a critical evaluation of LC/MS in environmental chemistry, written by experienced practitioners as a practical reference guide. An introductory section on fundamental aspects and instrumentation is followed by applications using most interfaces (particle beam, thermospray, electrospray). Analytes include pesticides, detergents, dyes, polar metabolites, waste streams, organo-tins and marine toxins.

Mass Spectrometry of Soils
T.W. Boutton, S. Yamasaki (eds.)

This single-source reference is the first interdisciplinary work of its kind on the subject. It provides detailed coverage of the applications of proven spectrometric techniques in soil science, and presents the analytical approaches required. It contains nearly 1200 bibliographic citations, figures, and equations.

Mass Spectrometry in the Biological Sciences
A.L. Burlingame, S.A. Carr (eds.)

Leading practitioners describe in detail advanced methods used in the analysis of biomacromolecules of natural and recombinant origin. They cover real-world problems in protein biochemistry, immunology, glycopathy and in the biochemistry of human bacterial pathogens, lipids and nucleic acids. The MS methods include MALDI TOF MS, electrospray, tandem techniques and FT/ICR. Database searching is also covered. A series of 10 appendices list useful reference data for the MS of peptides and carbohydrates.

Mass Spectrometry in Biomolecular Sciences
R.M. Caprioli, A. Malorni, G. Sindona (eds.)

This volume is in the NATO Science Series: C Mathematical and Physical Sciences (Vol. 475) and covers the Proceedings of the NATO Advanced Study Institute held in 1993 at Lacco Ameno, Ischia, Italy. It covers
technological and applied developments, and includes ionization techniques and ion analysis. The newer ionization methods are reviewed and major instrumentation involved in mass analysis is described. The on-line combination of GC, LC and supercritical fluid chromatography with MS is also included.

Protein and Peptide Analysis by Mass Spectrometry
J.R. Chapman (ed.)

In the Methods in Molecular Biology Series (No. 61), this book contains a comprehensive collection of MS methods for the analysis of peptides and proteins. Experts have contributed detailed step-by-step protocols covering topics such as recombinant protein analysis, peptide sequencing and quantification, analysis of glycoproteins and glycopeptides, measurement of drug loading on proteins, study of protein secondary structure, noncovalent interactions and using MS with PAGE.

B.L. Karger, W.S. Hancock (eds.)

With its companion Volume 271, they cover the fundamentals and applications of LC, electrophoresis and MS, with chapters written by experts in their fields. The MS chapters cover FAB MS, electrospray ionization MS, matrix-assisted laser desorption MS of proteins, and quadrupole ion trap MS.

B.L. Karger, W.S. Hancock (eds.)

The MS chapters in this volume cover protein structure analysis, carbohydrate sequence analysis by electrospray ionization MS, reversed-phase peptide mapping of recombinant human glycoproteins using LC/electrospray ionization MS, peptide characterization, capillary electrophoresis/MS, trace analysis peptide mapping by high-performance displacement chromatography and measuring DNA adducts by GC-electron capture/MS.

1996, Academic Press, 0-12-182172-2

Stable Isotopes in Human Nutrition
F. Mellon, B. Sandstrom (eds.)

In the Food Science and Technology International Series, this is a handbook of methodology dealing with the use of stable isotopes in human studies of absorption and the metabolism of essential mineral and trace elements. Sections cover nutritional techniques, sample handling and preparation, quantification of stable isotopes, and future developments. Quantification methods include electron ionization, GC/MS, FAB MS, thermal ionization MS and inductively coupled plasma MS.

Applications of Modern Mass Spectrometry in Plant Science Research
R.P. Newton, T.J. Walton (eds.)

The basic principles, techniques and capabilities of MS in the analysis of plant-derived compounds are covered. Ionization methods, MS/MS techniques, MALDI MS and electrospray MS are prominent. The types of compounds covered include proteins, DNA, RNA, lignins, phytohormones, cyclic nucleotides, flavonoid glycosides, fatty acid derivatives, tropane alkaloids and brassinosteroids. This book is in the series of the Proceedings of the Phytochemical Society of Europe.

Biofluid Assay for Peptide-related and Other Drugs. Methodological Surveys in Bioanalysis of Drugs, Vol. 24
E. Reid, H.M. Hill, I.D. Wilson (eds.)

This book describes state-of-the-art technology in the bioanalysis of drugs. The Assay Compendium contains a summary of literature based on therapeutic type, emphasizing more sensitive assays and automation. Approaches described for peptide-related drugs include immuno-based methods and MS methods, including MALDI MS, atmospheric pressure chemical ionization LC/MS, electrospray LC/MS and MS/MS techniques.

Mass Spectrometry for Biotechnology
G. Siuzdak

This covers the fundamental concepts of MS and how the instruments work, with descriptions of recent advancements. Also included are a glossary of basic terms, practical tips on using mass spectrometric techniques, and a simplified description of MS, including MALDI, electrospray and FAB.

Protein Sequencing Protocols
B.J. Smith (ed.)

In the Methods in Molecular Biology Series (No. 64), this book provides practical step-by-step details of techniques utilized for protein sequence analysis. Techniques covered include peptide isolation and mapping, amino acid
analysis, chemical and mass spectrometric approaches to N- and C-terminal sequencing, and analysis of sequence information.

Biochemical and Biotechnological Applications of Electrospray Ionization Mass Spectrometry. ACS Symposium Series No. 619
A.P. Snyder (ed.)
This book introduces improved characterization of proteins and biological molecules. The chapters include specific applications of electrospray ionization MS for analyzing proteins, peptides, glycolipids, lipopolysaccharides, oligodeoxynucleotides, nucleic acids, drugs and marine toxins.

The Protein Protocols Handbook
J.M. Walker (ed.)
This handbook offers comprehensive protocols for the analysis of proteins and peptides. The condensed techniques provided cover all of the basic methods regularly employed: 145 concise, step-by-step protocols which involve mainly chromatography and electrophoresis but with some MALDI and GC/MS.

Inductively Coupled and Microwave Induced Plasma Sources for Mass Spectrometry
E.H. Evans, J.J. Giglio, T.M. Castillano, J.A. Caruso
One of the RSC Analytical Chemistry Monographs, this book presents practical applications of the theory of inductively coupled plasma sources in a tutorial style, emphasizing the interfacing of microwave induced and inductively coupled plasma sources with MS, and interfacing chromatographic techniques.

New Methods in Peptide Mapping for the Characterization of Proteins
W.S. Hancock (ed.)
This is a volume in the Analytical Biotechnology Series, and is devoted to the characterization of recombinant DNA-derived proteins by peptide mapping. It describes new technological procedures, including capillary electrophoresis, analysis of glycopeptides and the use of electrospray and MALDI MS.

Steroid Analysis
H.L.J. Makin, D.B. Gower, D. Kirk (eds.)
This volume provides comprehensive and up-to-date information on the analysis of steroids, mainly in biological fluids. Chapters on the extraction, separation and quantification of steroids are followed by chapters describing the analysis of specific steroid groups, including mass spectrometric methods.

Chemical, Environmental and Biomedical Applications of Ion Trap Mass Spectrometry
R.E. March, J.F.J. Todd (eds.)
This is really the third volume in the ion trap series (see the two books in the section on Basic MS, by the same editors). This volume consists of 14 chapters in four parts: Fundamentals; Practical ion trap methodology; Applications involving small molecules; Environmental and Biomedical Applications.

Applied Pyrolysis Handbook
T.P. Wampler (ed.)
This comprehensive book on the instrumentation and analytical applications of pyrolysis includes sections on pyrolysis/GC, pyrolysis/GC/MS and pyrolysis/MS.

Forensic Applications of Mass Spectrometry
J. Yion
The techniques discussed include capillary GC/MS, thermospray LC/MS, MS/MS and pyrolysis. A variety of applications include analysis of body fluids and hair for drugs of abuse, drug testing in sports, analysis of accelerants in fire debris and protection of industrial products by isotopic signature.

Time-of-flight Mass Spectrometry. ACS Symposium Series No. 549
R.J. Cotter (ed.)
A comprehensive discussion of TOF MS examining the use of time-of-flight TOF instruments in tandem mode and their interfacing with continuous ionization techniques. It includes examples of applications to biological research.

Mass Spectrometry. Clinical and Biomedical Applications. Vol. 2
D.M. Desiderio (ed.)
This volume reviews novel instrumentation and techniques as applied to the analysis of diacylglyceryl-phospholipids, modifications to DNA, the characterization
of variant hemoglobins and urinary nucleosides. Microdialysis/MS is also featured. (See also Volume 1 below, 1992.)

Biological Mass Spectrometry. Present and Future
T. Matsuo, R.M. Caprioli, M.L. Gross, Y. Seyama (eds.)
This volume covers developments in the field of biological MS, including electrospay ionization, matrix-assisted laser desorption, LC/MS, ion trap MS and FT/ICR. It contains specific applications to proteins, drugs and natural products.

Time-of-Flight Mass Spectrometry and its Applications
E.W. Schlag (ed.)
This book was previously published as a special issue of the journal International Journal of Mass Spectrometry and Ion Processes (1994) and gives a survey of current applications from many active groups in the field.

Applications of Plasma Source Mass Spectrometry
G. Holland, A.N. Eaton (eds.)
This series of books represents the current state of plasma source MS in all its forms, and charts the latest developments in a wide range of applications. Special attention is given to inductively coupled plasma MS and glow discharge MS.

Mass Spectrometry for the Characterization of Microorganisms. ACS Symposium Series No. 541
C. Fenselau (ed.)
The book includes features on GC/MS for the clinical diagnosis of viral infection, and summarizes the status of detection of biological agents and of modifications in ribonucleic acids in microorganisms. It also describes electrospay, laser desorption and MS/MS for protein processing and modification in viruses.

Advances in Chemical Diagnosis and Treatment of Metabolic Disorders I
I. Matsumoto (ed.)
This book contains a cross-section of updated and revised papers (many GC/MS) from Symposia on Chemical Diagnosis of Metabolic Disorders held in Japan (1990, 1991).

Mass Spectrometry of Lipids
R.C. Murphy
This is a fundamental overview of the general physical concepts of MS that details the unique ion chemistry of specific lipids, ranging from the simple unsaturated fatty acids to more complex glycosphingolipids and glycerophospholipids.

Modern Methods and Applications in Analysis of Explosives
J. Yinon, S. Zitrin
This book discusses developments in techniques and methods for the analysis of explosives, and reviews recent applications. It contains a list of explosive compounds based on a survey of specialist laboratories all over the world. The contents include explosive compounds and mixtures, chromatographic methods, mass spectrometric methods, analysis of explosive residues, environmental analysis of explosives and detection of hidden explosives.

Mass Spectrometry. Clinical and Biomedical Applications. Vol. 1
D.M. Desiderio (ed.)
The first Volume offers a thorough exploration of significant advances in theoretical and experimental research and instrumentation. Topics include the principles and practice of electrospay, quantitative analysis of neuropeptides, in-born errors of metabolism and the use of carnitine and acylcarnitines in metabolic disease diagnosis and management. (See also Volume 2 above, 1994.)

Chemical Ionization Mass Spectrometry, 2nd edition
A.G. Harrison
This is a comprehensive review of chemical ionization MS applications in structural elucidation and quantitative analytical studies. Chemical ionization mass spectra of 13 classes of compounds are discussed in detail to illustrate the influence of functional groups on the spectra observed.

Mass Spectrometry in the Biological Sciences. A Tutorial
M.L. Gross (ed.)
This volume is in the NATO Science Series: C Mathematical and Physical Sciences (Vol. 353) and covers the Proceedings of the NATO Advanced Study Institute held in 1990 at Cetraro, Italy. It is divided into three
sections, dealing with instrumentation for mass analysis and detection, methods in MS and applications to biomolecules.

**Continuous-flow Fast Atom Bombardment Mass Spectrometry**

R.M. Caprioli (ed.)

This book is based on the presentations made at a workshop on continuous-flow FAB held in Annapolis, Maryland and, although fairly old, is included because there are so few books dealing with LC/MS as the main subject. The papers presented have been expanded and edited to form a small volume detailing advances in a number of key areas.

**Analytical Microbiology Methods. Chromatography and Mass Spectrometry**

A. Fox, S.I. Morgan, L. Larsson, G. Odham

This book covers a broad array of approaches for automated and rapid identification of microorganisms, characterization of microbial products and constituents and trace detection of microbial chemicals.

**Lasers and Mass Spectrometry**

D.M. Lubman (ed.)

In the Oxford Series in Optical and Imaging Sciences No. 1, each chapter deals with a particular application area and forms an entry point for the utilization of MS for graduate students and researchers.

J.A. McCloskey (ed.)

The first section covers a range of general techniques and topics of contemporary importance in the applications of MS to the biological sciences in general. The three remaining sections emphasize specific applications divided among three major classes of molecules: peptides and proteins, glycoconjugates, nucleotides and nucleosides. Each of these sections opens with a critical overview of the applications of MS to that area.

**Liquid Chromatography/Mass Spectrometry. Applications in Agricultural, Pharmaceutical and Environmental Chemistry. ACS Symposium Series No. 420**

M.A. Brown (ed.)

This volume describes the LC/MS techniques and instrumentation available and being used for analyzing agrochemicals, drugs, their metabolites and environmental pollutants. The analysis of pesticides, herbicides (chlorinated, sulfonylurea), antibiotics, retinoic acid, target and nontarget pollutants, phenols and phenol conjugates and polar urinary metabolites are included.

**Mass Spectrometry in Clinical Biochemistry**

A.M. Lawson (ed.)

This book serves as a reference handbook of applications of MS to the practice of clinical biochemistry. Applications to the work of specialized laboratories are discussed, covering subjects such as endocrinology, psychiatry, pediatrics, immunology, nutrition and others that embrace clinical biochemistry.

**Mass Spectrometry**

M.E. Rose (ed.)

This Specialist Periodical Report series is now discontinued. It provided full reviews on the MS literature published over 2-year periods.

**ACKNOWLEDGMENTS**

The author gratefully acknowledges the invaluable assistance of the publishers of the featured printed and electronic products in the preparation of this article and for access to Web-based products.

</table>

The quadrupole ion trap is constructed of three electrodes that, when held at appropriate potentials, cause the formation of a trapping pseudo-potential well so that charged particles, or gaseous ions, may be confined or stored for long periods of time. The two end-cap electrodes resemble saucers while the ring electrode resembles a napkin ring; all of the electrodes are of hyperbolic geometry. The ion trap itself functions as a mass spectrometer when the ion-confining conditions are modified such that ions are ejected mass-selectively from the trapping potential well. As ions of successive mass/charge ratios are ejected in turn from the ion trap, they impinge upon an external detector whereby ion signals are created in proportion to the ion number of each species; in this manner, a mass spectrum is generated. The QITMS (quadrupole ion trap mass spectrometer) is an extraordinary instrument in that it is physically small (the entire electrode assembly can be held in the palm of one’s hand) compared with magnetic and electric sector instruments, it is relatively inexpensive, it is one of the most, if not the most, sensitive mass spectrometers and, since several mass-selective operations can be carried in succession, the ion trap can function as a tandem mass spectrometer. Tandem mass spectrometric operation is described as (MS)$^n$. With the QITMS, (MS)$^n$ is carried out in time in the same volume of space whereas (MS)$^n$ in sector instruments is carried out in space. With sector instruments, the maximum value of $n$ is $n = 4$ yet with the ion trap, (MS)$^n$ where $n = 4–6$ can be carried out routinely and $n = 13$ has been achieved. The QITMS shares several similarities with the ion cyclotron resonance mass spectrometer yet the cost of the former is about one-tenth that of the latter. One striking difference between the QITMS and all other mass spectrometers is that the QITMS operates at a pressure of $10^{-3}$ Torr compared with $10^{-6}–10^{-9}$ Torr for other mass spectrometers.

The theory of ion confinement and ion trajectory manipulation in the QITMS has been explained relatively simply so far. Since the theory differs widely from those of sector instruments and ion cyclotron resonance mass spectrometry (ICR/MS), it will not be familiar to those who have not had the opportunity to examine ion motion in quadrupole fields. Optimum operation of the QITMS is effected by collisional focusing of the ion cloud to the center of the ion trap under the influence of helium buffer gas. Since the movement of ions confined in the ion trap is periodic, the trajectories of collisionally focused ions can be expanded by resonance excitation effected by the imposition of supplementary radio frequency (rf)
potentials of low amplitude to the end-cap electrodes of the ion trap. This excitation operation permits isolation of selected ion species, by ejection of unwanted ion species, followed by selective ion/molecule reaction or by collision-induced dissociation (CID) with subsequent mass analysis of the product/fragment ions formed. Sample calculations are given of all of the relevant trapping parameters. Applications of the QITMS as a single stage mass spectrometer and as a tandem mass spectrometer are discussed. The operation of the QITMS for the identification of dioxins and furans co-eluting from a gas chromatograph is described. In addition, the application of chemical ionization (CI) for the identification of co-eluting polychlorinated biphenyl (PCB) congeners is discussed. The QITMS is an extraordinary instrument that is capable of great sensitivity, high mass range and high mass resolution. Since the QITMS is compatible with methods for generating ions externally, such as electrospray ionization (ESI), its continued growth in many areas of mass spectrometry (MS) is assured.

1 INTRODUCTION

The QITMS functions not only as a mass spectrometer of high sensitivity and high specificity but also as an ion store in which gaseous ions can be confined for periods of some hundreds of milliseconds; both functions are employed in normal ion trap operation. While other mass spectrometers operate at pressures <10⁻⁶ Torr, the ion trap operates at a pressure of 1 mTorr of helium buffer gas. As a storage device, the ion trap acts as an “electric field test tube” for the confinement of gaseous ions, either positively charged or negatively charged, in the absence of solvent molecules. The confining capacity of the ion trap arises from the formation of a trapping potential well when appropriate potentials are applied to the electrodes of the ion trap. As an ion storage device, the ion trap permits the study of gas-phase ion chemistry and the dissociation of ions for elucidation of ion structures. When stages of mass selectivity are employed repeatedly, the ion trap functions as a tandem mass spectrometer.

The ion trap functions as a mass spectrometer when the field within the device is changed, so that the trajectories of simultaneously trapped ions of consecutive specific mass/charge ratio (m/z) become sequentially unstable, and ions leave the trapping field in order of mass/charge ratio. Upon ejection from the ion trap, ions strike a detector and provide an output signal. This relatively simple method of mass-selective operation of the ion trap has led to a revolution in MS. It is estimated that some 4500 ion trap instruments have been sold thus far at a total cost of about a quarter of a billion US dollars; the volume of these sales has led to a reorganization of the MS industry. The combination of a quadrupole ion trap interfaced with a gas chromatograph is now available commercially at a price which permits the acquisition of these instruments by most academic departments of chemistry; thus these instruments are now becoming accessible to relatively large numbers of students, both graduate and undergraduate.

With the advent of new methods by which ions can be formed in the gas phase from polar as well as covalent molecules and introduced subsequently into an ion trap, the range of applications of the quadrupole ion trap is now considerable. The coupling of liquid chromatography (LC) with ESI and with MS in the early 1980s, together with the rapid advancement in ion trap technology, have led to the development of new ion trap instruments for the analysis of nonvolatile, polar, and thermally labile compounds. In 1995, new ion trap instruments (Finnigan’s LCQ™ and GCQ™, and Bruker-Franzen’s ESQUIRE™) were introduced which employ external ion sources with injection of externally generated ions into the ion trap. The major focus for the application of these new instruments, using LC/ESI/MS (liquid chromatography/electrospray ionization mass spectrometry), has been the analysis of high-molecular-weight biopolymers such as proteins, peptides, and oligodeoxyribonucleotides.

2 STRUCTURE OF THE QUADRUPOLE ION TRAP MASS SPECTROMETER

The quadrupole ion trap consists essentially of three electrodes which are shown in open array in Figure 1. Two
of the three electrodes are virtually identical and, while having hyperboloidal geometry, resemble small inverted saucers; these saucers are called end-cap electrodes and in Figure 1 are distinguishable by the number of holes in the center of each electrode. One end-cap electrode has a single small central aperture through which electrons and/or ions can be gated periodically while the other has several small apertures arranged centrally also and through which ions pass to a detector; in ion trap instruments with external ion sources, each end-cap electrode has a single perforation. The third electrode is also of hyperboloidal geometry (of two sheets, in this case, rather than one) and is called the ring electrode; it not only resembles a serviette or napkin holder but is of roughly the same size in that the radius in the central plane, \( r_0 \), of the ring electrode is approximately 1 cm. The ring electrode is positioned symmetrically between the two end-cap electrodes as shown in Figure 2; Figure 2(a) shows a photograph of an ion trap cut in half along the axis of cylindrical symmetry, while Figure 2(b) is a cross-section of an ideal ion trap showing the asymptotes and the dimensions \( r_0 \) and \( z_0 \), where \( 2z_0 \) is the separation of the two end-cap electrodes measured along the axis of the ion trap.

The electrodes in Figure 2 are necessarily truncated for practical purposes but, in theory, they extend to infinity and meet the asymptotes shown in Figure 2. The asymptotes arise from the hyperboloidal geometries of the three electrodes and, in the ideal case, are inclined at an angle of 53° 34’ to the cylindrical axis (the \( z \)-axis) of the electrode arrangement. The geometries of the electrodes have been chosen so as to produce a near ideal quadrupole field when an rf potential is applied to the ring electrode and the two end-cap electrodes are grounded. In a quadrupole field, the forces acting on an ion depend linearly upon the displacement, \( x \), \( y \), or \( z \) from the ion trap center.

In Figure 3 is shown a representation of the instantaneous saddle-shaped potential surface generated by the application of an rf potential of, say, 1000 \( V_{0-p} \) (zero-to-peak) to the ring electrode; the open circle represents an ion on this surface. Because of the cylindrical symmetry of the ion trap, the \( x \)- and \( y \)-components of the field are often combined to yield a single radial \( r \)-component using \( x^2 + y^2 = r^2 \). As the rf potential oscillates sinusoidally with a frequency of the order of 1 MHz, the field is periodically reversed; this situation can be envisaged as Figure 3 inverted with, say, \(-1000 \ V_{0-p}\) applied to the ring electrode and the end-cap electrodes grounded. The ion in Figure 3 rolls down the slope and approaches the ion trap center radially, that is, the ion is being focused towards the center; the ion may continue to roll downhill and moves axially away from the center, that is, the ion is being defocused. Upon reversal of the field in Figure 3, the ion is defocused radially and focused axially. When the focusing and defocusing forces are balanced by the imposition of appropriate conditions, the ion can remain confined on the surface as
though it were trapped in a pseudo-potential well. Thus, a trapping pseudo-potential well, parabolic in cross-section, can be created when an rf potential is applied to the ring electrode and the two end-cap electrodes are grounded.

The trapping pseudo-potential well is shown in Figure 4; the potential well in the axial direction is of depth $D_z$, while in the radial direction the depth is $D_r$. The value of $D_z$ is about twice that of $D_r$, so that the potential well resembles more a flower vase than it does a bowl. The depth of the trapping pseudo-potential well represents a measure of the kinetic energy that is required in order for an ion to escape the well; for an ion of $m/z$ 200, under the conditions of Figure 3, the kinetic energy required is ca. 58 eV.

In the ion trap, the trajectory or path of an ion is characterized by two frequencies, or secular frequencies, that arise from the axial and radial motions of the ion induced by the trapping field. At a given instant of time, an ion is focused axially towards the center of the ion trap while it is simultaneously defocused radially so that it moves away from the ion trap center; some half a microsecond later the situation is reversed, and so on. The resultant trajectory from these axial and radial oscillations resembles a figure-of-eight; such a figure is known as a Lissajous figure. A Lissajous figure can be demonstrated readily with a light beam reflected in turn from each of two mirrors, $M_1$ and $M_2$ attached respectively to two tuning forks, $F_1$ and $F_2$, arranged orthogonally as shown in Figure 5. In the case of the ion trajectory, there is a high-frequency ripple superimposed on the Lissajous figure; the ripple is due to the rf potential that oscillates at 1 MHz.

In Figure 6(a) is shown the trajectory of a single ion in an ion trap; an enlargement of this trajectory is shown in Figure 6(b) where the Lissajous-type motion and the high-frequency ripple are seen clearly. The projection of the trajectory onto the $x$–$y$ plane forms a straight line as shown in Figure 6(b); this line shows that the ion motion is restricted to a plane.

Mass-selective ejection of ions from the potential well within the ion trap is accomplished by ramping in a linear fashion the amplitude of a rf potential applied to one of the ion trap electrodes; each ion species is ejected from the potential well at a specific rf amplitude and, because the initial amplitude and ramping rate are known, the mass/charge ratio can be determined for each ion species upon ejection. This relatively simple method for measuring the mass/charge ratios of confined ions upon ejection was developed by Stafford et al.\(^2\) and is known as the “mass-selective axial instability mode”; this method made possible the commercialization of the quadrupole ion trap around 1984. A prerequisite of this method of mass-selective ion ejection is that ions be herded initially to the center of the ion trap under the action of momentum-dissipating collisions; helium atoms are used for this purpose.
3 LITERATURE

The quadrupole ion trap and the related quadrupole mass filter were invented by Paul and Steinwedel\(^1\) in 1960 and their pioneering work was recognized by the award of a 1989 Nobel Prize in Physics to Wolfgang Paul.\(^4\) Yet the basis of the theory of operation of quadrupole devices was laid down about 140 years ago by Mathieu to whose work we shall return. In this presentation, references are given to those works that are regarded as landmarks in the field of ion trap MS and to those publications that have been used to illustrate specific modes of operation of the ion trap.

Detailed accounts of the early development of the quadrupole-type devices as mass spectrometers were published by Dawson and Whetten\(^5\) and by Dawson\(^6\) the latter publication has now been reprinted as part of the series of “American Vacuum Society Classics” by the American Institute of Physics under ISBN 1563964554. A full treatment of ion trap theory can be found in the now standard but somewhat dated text by March, Hughes and Todd;\(^7\) the historical account in this text by Todd has been expanded into a full-scale review.\(^8\) Other reviews on specific topics have been contributed by Cooks, et al.\(^9,10\) and a special collection of papers reporting upon recent developments has appeared also.\(^11\)

The field of quadrupole ion trap MS was reviewed extensively for the 12th International Mass Spectrometry Conference,\(^12\) held in Amsterdam in 1991. Since that time, three volumes have been published in the CRC Series on Modern Mass Spectrometry.\(^13\) Volume 1 of this series covers the history of the quadrupole ion trap, nonlinear ion traps, ion activation, ion/molecule reactions and ion trajectory simulations; the reader is referred to Chapter 2 of Volume 1 for a detailed exposition of the mathematical basis of the operation of the ion trap. Volume 2 deals with enhancement of ion trap performance, ion trap confinement of externally generated ions, ion structure differentiation, ion photodissociation, lasers and the ion trap, and ion traps in the study of physics. Volume 3 includes a review of fundamentals in addition to extensive expositions on gas chromatography/ion trap tandem mass spectrometry (GC/MS/MS) and liquid chromatography/ion trap tandem mass spectrometry (LC/MS/MS); examples of applications in each of the three areas above are given. In all, the above three volumes contain 30 chapters that originated from 18 of the leading ion trap research laboratories. An introduction to the quadrupole ion trap written by this author in a tutorial form has appeared.\(^14\)

4 TRAPPING PSEUDO-POTENTIAL WELL

In a quadrupole ion trap, ions are focused by collisions with helium buffer gas towards the center of the ion trap. This focusing process imposes a degree of order upon the ions much like that of a flock of sheep that has been shepherded together by sheepdogs. Ions of lowest mass/charge ratio have the smallest excursions from the center of the ion trap so that they reside closest to the ion trap center; since these ions have the least kinetic energy, they populate the lowest region in the potential well. The ions of next higher mass/charge ratio have the smallest excursions from the center of the ion trap so that they reside closest to the ion trap center; since these ions have the least kinetic energy, they populate the lowest region in the potential well. The ions of next higher mass/charge ratio are arranged in the ion trap about the ions of lowest mass/charge ratio and populate the next higher region of the potential well, and so on. Under these conditions, trapped ion species are arranged about the ion trap center rather like the layers
of an onion with the ions of lowest mass/charge ratio residing in the center of the onion. Mass-selective ion ejection in order of increasing mass/charge ratio requires that ions of lowest mass/charge ratio be ejected first so that the mass-selective ion ejection process is akin to removing the layers of the onion, one by one, starting with the layer nearest the onion center.

When ions of lowest mass/charge ratio are extracted from the center of the onion, they experience space charge perturbation while passing through the layers of ions of higher mass/charge ratio, become spatially dispersed and, upon ejection, produce ion signals with poor mass resolution. To obviate this problem, ions of lowest mass/charge ratio are made to come into resonance with a fixed frequency applied across the end-cap electrodes. Ions come into resonance as the rf amplitude is ramped, that is, as the amplitude is increased. As the ions become excited resonantly in the axial direction, they emerge from the onion and experience a brief period free of space charge immediately prior to ejection. During ejection, the ions remain clustered together and, upon impacting on the detector, produce ion signals of higher mass resolution. This process of ion axial excitation prior to ion ejection is termed axial modulation.

Let us consider an analogy to this trapping, focusing, and ejection process. The trapping pseudo-potential well created within the electrode assembly of the quadrupole ion trap can be likened to a bowl or glass of parabolic cross-section; ion species are confined in layers in the bowl rather like an exotic drink of several liqueurs arranged carefully and tastefully in horizontal layers according to their density, as shown in Figure 7. The liqueur of greatest density represents the ions of lowest mass/charge ratio. The tilting of the bowl or the lowering of the side of the bowl corresponds to the ramping of the rf amplitude; the liqueur glass in Figure 7 corresponds to the detector. The removal of ions from near the bottom of the potential well is effected with the straw in Figure 7. The tilting of the bowl is analogous to ramping the rf amplitude while the use of a straw is analogous to axial modulation in which ions are brought successively into resonance with an applied AC (alternating current) frequency, as is discussed later. As the liqueurs are drawn up the straw in order of decreasing density, so the ions are ejected in order of increasing mass/charge ratio and impinge upon a detector. The signals from the detector create a mass spectrum of the contents of the ion trap.

5 STRUCTURE OF THE QUADRUPOLE ION TRAP

The quadrupole ion trap is composed of three electrodes with the ring electrode located symmetrically between two end-cap electrodes as shown in Figure 2. The shape of the ring electrode is given by Equation (1)

$$\frac{r^2}{r_0^2} - \frac{z^2}{z_0^2} = 1$$

(1)

while the shapes of the end-cap electrodes are given by Equation (2)

$$\frac{r^2}{r_0^2} - \frac{z^2}{z_0^2} = -1$$

(2)

For an ideal quadrupole field, the following identity is given (usually with more authority than truth)

$$r_0^2 = 2z_0^2$$

(3)

so that, once the magnitude of \( r_0 \) is given, the sizes of all three electrodes and the spacing between the electrodes are fixed. However, it has been pointed out by Knight\(^{15}\) that, contrary to Equation (3), the ratio of \( z_0^2 : r_0^2 \) is not necessarily restricted to 2. Regardless of the value of this ratio, the size of the ion trap, is determined largely by the magnitude of \( r_0 \) and, in the majority of commercial ion traps in use today, \( r_0 \) is either 1.00 cm or 0.707 cm.

6 THEORY OF QUADRUPOLE ION TRAP OPERATION

The motions of ions in quadrupole devices differs greatly from the straight lines and arcing curves of ions in field-free regions and in magnetic and electrostatic sectors, respectively, familiar to those conversant with sector mass spectrometers. The quadrupole ion trap and
the quadrupole mass filter or analyzer are described as dynamic instruments since ion trajectories in these instruments are influenced by a set of time-dependent forces (which render the trajectories mathematically more difficult to predict compared with sector instruments). Sector instruments are described as static devices in that the field is maintained at a constant value for transmission of an ion. In quadrupole instruments, a quadrupole field is established when a potential is applied to electrodes that have a hyperbolic geometric form. Let us examine the movement of charged particles in a quadrupole field by considering first the forces acting on a single ion within a quadrupole field.

6.1 An Ion in a Quadrupole Field

An ion, positively charged or negatively charged, in a quadrupole field experiences strong focusing in that the restoring force, which drives the ion back towards the center of the device, increases as the ion deviates from the center of the device. The motion of ions in a quadrupole field can be described mathematically by the solutions to the second-order linear differential equation described originally by Mathieu;\(^\text{16}\) this equation is known as the Mathieu equation. From Mathieu’s investigation of the mathematics of vibrating stretched skins, he was able to derive solutions in terms of regions of stability and instability; these solutions and the criteria for stability and instability have been used to describe the trajectories of ions confined in quadrupole devices and to define the limits to trajectory stability. In order to adopt the solutions to the Mathieu equation, we must verify that the equation of motion of an ion confined in a quadrupole device can be described by the Mathieu equation. The path that is followed here concerns the expression for a force (mass \(\times\) acceleration) in Mathieu’s equation, and comparison of that expression with one for the force on an ion in a quadrupole field. This comparison is laid out below in simple mathematical terms; thus it is possible to express the magnitudes and frequencies of the potentials applied to ion trap electrodes, the size of the ion trap, and the mass/charge ratio of ions confined therein in terms of Mathieu’s dimensionless parameters, \(a_u\) and \(q_u\). On this basis, we shall adopt the idea of stability regions in \(a_u, q_u\) space in order to discuss the trapping, and limits thereto, of gaseous ions in quadrupole devices.

6.2 The Mathieu Equation

The canonical or commonly accepted form of the Mathieu equation is, Equation (4):

\[
d\frac{d^2u}{dx^2} + (a_u - 2q_u \cos 2\xi)u = 0
\]

where \(u\) represents the coordinate axes \(x, y\) and \(z\), \(\xi\) is a dimensionless parameter equal to \(\Omega t/2\) such that \(\Omega\) must be a frequency as \(t\) is time, and \(a_u\) and \(q_u\) are additional dimensionless parameters known as trapping or stability parameters. The introduction of \(\Omega\) here is not entirely serendipitous since it will reappear as the radial frequency (in \text{rad s}^{-1}) of the rf potential applied to the ring electrode. Now it can be shown by substituting \(\xi = \Omega t/2\) (from Equation 4) that

\[
d\frac{d^2u}{dx^2} = \frac{\Omega^2}{4} \frac{d^2u}{d\xi^2}
\]

Substitution of Equation (5) into Equation (4), multiplying throughout by \(m\) and rearranging yields

\[
m \frac{d^2u}{dx^2} = -m\Omega^2 (a_u - 2q_u \cos \Omega t)u
\]

We note that the left side of Equation (6) can represent the force on an ion, that is, mass times acceleration in each of the \(x, y\) and \(z\) directions.

Now the field in quadrupole devices is uncoupled so that the forces in the three coordinate directions may be determined separately. Let us then consider the force in the \(x\)-direction, \(F_x\), experienced by an ion of mass \(m\) and charge \(e\) at any point within a quadrupole field, Equation (7)

\[
F_x = ma = m \frac{d^2x}{dt^2} = -e \frac{\partial \phi}{\partial x}
\]

where \(a\) is the acceleration of the ion, \(e\) is the electronic charge and \(\phi\) is the potential at any point \((x, y, z)\) within the field. Similar expressions for \(F_y\) and \(F_z\) can be obtained. It should be noted that Equation (7) relates the force on an ion to the field within the ion trap. The quadrupole potential \(\phi\) can be expressed as

\[
\phi = \frac{\phi_0}{r_0^3} (\lambda x^2 + \sigma y^2 + \gamma z^2)
\]

where \(\phi_0\) is the applied electric potential (which we shall see later is an rf potential either alone or in combination with a direct current (DC) potential), \(\lambda, \sigma\) and \(\gamma\) are weighting constants for the \(x, y, z\) coordinates, respectively, and \(r_0\) is a constant which is defined separately depending on whether the quadrupole device is an ion trap or mass filter. It can be seen from Equation (8) that the potential increases quadratically with \(x, y, z\). In any electric field, it is essential that the Laplace condition, which requires that the second differential of the potential at a point be equal to zero, be satisfied; the Laplace condition ensures that the field in the \(x, y, z\) directions is linear and does not change. When that is done, it is found that, Equation (9)

\[
\lambda + \sigma + \gamma = 0
\]
For the ion trap, \( \lambda = \sigma = 1 \) and \( \gamma = -2 \), whereas for the quadrupole mass filter \( \lambda = -\sigma = 1 \) and \( \gamma = 0 \). Substituting the values \( \lambda = \sigma = 1 \) and \( \gamma = -2 \) into Equation (8), we obtain Equation (10) for the potential at any point within the quadrupole field in a quadrupole ion trap.

\[
\phi_{x, y, z} = \frac{Q_0}{r_0^2} (x^2 + y^2 - 2z^2) \tag{10}
\]

This equation can be transformed into cylindrical coordinates by employing the standard transformations \( x = r \cos \theta, y = r \sin \theta, z = z \). Thus Equation (10) becomes Equation (11)

\[
\phi_{r, z} = \frac{Q_0}{r_0^2} (r^2 \cos^2 \theta + r^2 \sin^2 \theta - 2z^2) \tag{11}
\]

When we apply the trigonometric identity \( \cos^2 \theta + \sin^2 \theta = 1 \), we obtain Equation (12)

\[
\phi_{r, z} = \frac{Q_0}{r_0^2} (r^2 - 2z^2) \tag{12}
\]

The applied electric potential, \( Q_0 \), (that is, applied to the ring electrode) is either an rf potential \( V \cos \Omega t \) or a combination of a DC potential, \( U \), of the form, Equation (13)

\[
\phi_0 = U + V \cos \Omega t \tag{13}
\]

where \( \Omega \) is the angular frequency (in rad s\(^{-1}\)) of the rf field. Note that \( \Omega \) is equal to \( 2\pi f \), where \( f \) is the frequency in hertz.

When the expression for \( \phi_0 \) as given by Equation (13) and \( \lambda = 1 \) are substituted into Equation (8) and \( \phi \) is differentiated with respect to \( x \), Equation (14) is obtained for the potential gradient

\[
\frac{\partial \phi}{\partial x} = \frac{2x}{r_0^2} (U + V \cos \Omega t) \tag{14}
\]

Substitution of Equation (14) into Equation (7) yields an expression for the force on an ion, Equation (15)

\[
m \frac{d^2 x}{dt^2} = -\frac{8eU}{mr_0^2 \Omega^2} (U + V \cos \Omega t)x \tag{15}
\]

We can now compare directly the terms on the right hand sides of Equations (6) and (15), recalling that \( u \) represents \( x \), to obtain, Equation (16)

\[
a_x = \frac{8eU}{mr_0^2 \Omega^2}; \quad q_x = \frac{-4eV}{mr_0^2 \Omega^2} \tag{16}
\]

When this derivation is repeated to obtain the force on an ion in the \( y \)-direction in a quadrupole mass filter, one finds that \( q_y = -q_x \); this relationship is obtained since \( \lambda = -\sigma = 1 \). For the quadrupole ion trap, it is found that \( q_x = q_z \); this equality is found since \( \lambda = \sigma = 1 \). It is suggested that it would be instructive for the reader to derive similarly the \( a_x \) and \( q_x \) trapping parameters for positively charged ions (Equation 17) which are used frequently in discussions of the stability diagram of the quadrupole ion trap; in this case, \( \lambda = \sigma = 1 \) and \( \gamma = -2 \). For negatively charged ions, the signs of the \( a_x \) and \( q_x \) trapping parameters in Equation (17) are reversed:

\[
a_x = -\frac{8eU}{mr_0^2 \Omega^2}; \quad q_z = \frac{4eV}{mr_0^2 \Omega^2} \tag{17}
\]

Let us ignore \( a_z \) (which is proportional to \( U \), a DC potential) for the present since most commercial ion trap instruments do not offer the flexibility of applying a DC potential to the electrodes; therefore, \( a_z \) is held equal to zero such that the most common mode of ion trap operation is said to correspond to operation on the \( q_z \) axis. The expression for \( q_z \) in Equation (17) contains the mass/charge ratio for a given ion, the size of the ion trap, \( r_0 \), the amplitude \( V \) of the rf potential and the radial frequency \( \Omega \); these parameters are all that we shall need in order to understand the various operations of the ion trap. The solutions to the Mathieu equation can be calculated in terms of \( a_z \) and \( q_z \) and these solutions can be interpreted in terms of trajectory stability (and instability) in each of the \( x, y \) (or \( r \)), and \( z \) directions. When the confinement conditions correspond simultaneously to trajectory stability in both \( r \)- and \( z \)-directions, a charged particle may be stored. The trajectories of a charged particle are characterized by the fundamental secular frequencies of ion motion in the radial, \( r \), and axial, \( z \), directions.

### 6.3 Potentials on the Electrodes

The potentials on the ring and end-cap electrodes may be verified in the following manner with reference to Figure 2 and Equation (12). Consider the intersection of the central radial plane with the surface of the ring electrode, such that \( z = 0 \) and \( r = r_0 \); the potential at the ring electrode is given by Equation (18)

\[
\phi_{r_0, 0} = \frac{\phi_0 r_0^2}{r_0^2} = \phi_0 \tag{18}
\]

Now consider the intersection of the central axis of cylindrical symmetry with the surface of either end-cap electrode, such that \( r = 0 \) and \( z = z_0 \); recalling the identity of Equation (3) and the potential of Equation (12), the potential at each end-cap electrode is given by Equation (19)

\[
\phi_{0, z_0} = \frac{\phi_0 r_0^2}{r_0^2} (-2z_0^2) = -\phi_0 \tag{19}
\]
However, no commercial quadrupole ion trap is operated in this fashion; rather, the end-cap electrodes are held at ground potential (except for the imposition of oscillating potentials of low amplitude, hundreds of millivolts to a few volts). The net effect of applying \( \phi_0 \) to the ring electrode and grounding the end-cap electrodes is to halve the mass range of the ion trap as a mass spectrometer.

In order to verify the potentials on the ring and end-cap electrodes in the commercial ion trap, an alternative equation to Equation (12) must be used; this equation is

\[
\phi_{r,z} = \frac{\phi_0 (r^2 - 2z^2)}{2r_0^2} + c
\]

(20)

where \( c \) is a constant. The ring electrode potential (Equation (20) with \( z = 0, r = r_0 \)) is given by Equation (21)

\[
\phi_{r,0} = \frac{\phi_0 r_0^2}{2r_0^2} + c = \phi_0
\]

from which we obtain \( c = \phi_0 / 2 \). The potential at the end-cap electrodes (\( r = 0 \) and \( z = z_0 \)) is given by Equation (22)

\[
\phi_{0,z} = -\frac{2\phi_0 z_0^2}{2r_0^2} + \frac{\phi_0}{2} = 0
\]

(22)

Hence Equation (20) reduces to Equation (23)

\[
\phi_{r,z} = \frac{\phi_0 (r^2 - 2z^2)}{2r_0^2} + \frac{\phi_0}{2}
\]

(23)

The constant term does not change the equations of motion derived from the partial differentials, but the potential along the asymptotes of the hyperbolas is changed. It should be noted that an ion at the center of a commercial ion trap experiences a potential of \( \phi_0 / 2 \) and “sees” a potential of \( -\phi_0 / 2 \) on the end-cap electrodes and a potential of \( \phi_0 / 2 \) on the ring electrode.

### 6.4 Stretched Ion Trap

As we discussed above, the electrodes of the ion trap are truncated in order to obtain a practical working instrument but this truncation introduces higher order multipole components to the potential as shown in Equation (24)

\[
\phi_{r,z} = C_0^0 + C_1^0 z + C_2^0 \left( \frac{1}{2} r^2 - z^2 \right) + C_3^0 z \left( \frac{3}{2} r^2 - z^2 \right) + C_4^0 \left( \frac{5}{2} r^2 - 3r^2 z^2 + z^4 \right) + \cdots
\]

(24)

The \( C_n^0 \) coefficients, where \( n = 0, 1, 2, 3, \) and \( 4 \), correspond to monopole, dipole, quadrupole, hexapole and octopole components, respectively, of the potential \( \phi_{r,z} \). For the pure quadrupole ion trap, only the coefficients corresponding to \( n = 0 \) and \( n = 2 \) are nonzero.

In order to compensate for these higher order multipole components, the electrodes of most commercial instruments were assembled in such a way that the distance between the end-cap electrodes was increased or “stretched”; the value of \( z_0 \) was increased by 10.6%. However, there was no corresponding modification of the shapes of the electrodes which would be required in order to maintain a purely quadrupolar geometry.

The immediate consequences are that the asymptotes to the end-cap electrodes no longer coincide with those for the ring electrode. Furthermore, \( r_0^2 \neq 2z_0^2 \). In order to compensate, in part, for the stretching of the ion trap, the trapping parameters are now calculated using the actual values of \( z_0 \) and \( r_0 \), as follows, Equation (25)

\[
a_r = \frac{8eU}{m(r_0^2 + 2z_0^2) \Omega^2}; \quad q_r = -\frac{4eV}{m(r_0^2 + 2z_0^2) \Omega^2}
\]

and

\[
a_z = -\frac{16eU}{m(r_0^2 + 2z_0^2) \Omega^2}; \quad q_z = \frac{8eV}{m(r_0^2 + 2z_0^2) \Omega^2}
\]

(26)

When \( r_0^2 = 2z_0^2 \) (Equation 3) is substituted into Equation (26), we obtain the trapping parameters given in Equation (17). It should be noted that for the ion trap in the LCQ™ and GCQ™ instruments, \( r_0 = 0.707 \text{ cm} \) and \( z_0 = 0.785 \text{ cm} \) such that the geometry has been stretched by ca. 57%.

### 7 REGIONS OF ION TRAJECTORY STABILITY

The operation of the quadrupole ion trap is concerned with the criteria that govern the stability (or instability) of the trajectory of an ion in the ion trap, that is, the experimental conditions that determine whether an ion is stored within the device or whether it is ejected and whether it is excited resonantly or not. The experimental conditions for the manipulation of ion trajectories are represented mathematically by the solutions to Mathieu’s equation.

The solutions to Mathieu’s equation are of two types: (i) ion motion is periodic but unstable, and (ii) ion motion is periodic and stable. Solutions of type (i) are called Mathieu functions of integral order and form the boundaries of unstable regions on the stability diagram. The boundaries, which are referred to as characteristic curves or characteristic values, correspond to the values of a new trapping parameter, \( \beta_z \), that is, \( 0, 1, 2, 3, \ldots \). \( \beta_z \) is a complex function of \( a_z \) and \( q_z \) to which we shall return. The boundaries represent, in practical terms, the point at which the trajectory of an ion becomes unbounded.
Solutions of type (ii) determine the motion of ions in an ion trap. The stability regions corresponding to stable solutions of the Mathieu equation in the $z$-direction are shaded and labeled “$z$-stable” in Figure 8(a). The stability regions corresponding to stable solutions of the Mathieu equation in the $r$-direction are shaded and labeled “$r$-stable” in Figure 8(b); it can be seen that they are doubled in magnitude along the ordinate and inverted. It is seen from Equations (25) and (26) that $a_z = 2 a_u$ and $q_z = -2 q_u$, that is, the stability parameters for the $r$- and $z$-directions differ by a factor of $-2$.

7.1 Stability Region

Ions can be stored in the ion trap provided that their trajectories are stable in the $r$- and $z$-directions simultaneously; such trajectory stability is obtained in the region closest to the origin, that is, region A in Figure 9 which is plotted in $a_u, q_u$ space, that is, where $a_u$ is plotted against $q_u$. Regions A and B are referred to as stability regions; region A is of the greatest importance at this time (region B remains to be explored) and is shown in greater detail in Figure 10. The coordinates of the stability region in Figure 10 are the Mathieu parameters $a_z$ and $q_z$. Here, we plot $a_z$ versus $q_z$ rather than $a_u$ versus $q_u$ which is unnecessarily confusing because $u = r, z$. In Figure 10, the $\beta_z = 1$ stability boundary intersects with the $q_z$ axis at $q_z = 0.908$; this working point is that of the ion of lowest mass/charge ratio (that is, low-mass cut-off (LMCO), as discussed below) which can be stored in the ion trap. The stability diagram for negatively charged ions is the mirror image about the $q_z$-axis of the stability diagram in Figure 10.

7.2 Secular Frequencies

A three-dimensional representation of an ion trajectory in the ion trap, as shown in Figure 6, has the general appearance of a Lissajous curve or figure-of-eight composed of two fundamental frequency components, radial and axial, respectively, $w_{r,0}$ and $w_{z,0}$ of the secular motion. The description of “fundamental” infers that there exist other higher order ($n$) frequencies and that the entire family of frequencies is described by $w_{r,n}$ and $w_{z,n}$. These secular frequencies are given by Equations (27) and (28):

$$ w_{r,n} = (n + \frac{1}{2} \beta_u) \Omega, \quad 0 \leq n < \infty $$  \hspace{1cm} (27)

$$ w_{z,n} = - (n + \frac{1}{2} \beta_u) \Omega, \quad -\infty < n < 0 $$  \hspace{1cm} (28)
for
simply as
simultaneous stability in both the r- and z-directions near the origin for the three-dimensional quadrupole ion trap; the iso-βz and iso-βr lines are shown in the diagram. The qz-axis intersects the βz = 1 boundary at qz = 0.908, which corresponds to qmax in the mass-selective instability mode.

\[ \beta_u \approx \left( a_u + \frac{q_u^2}{2} \right) \]  

(29)

where \( q_z < 0.2 \) and \( q_z < 0.4 \). It should be noted that while the fundamental axial secular frequency, \( w_{z,0} \), is usually given in units of hertz in the literature and referred to simply as \( w_z \), it should be given in radians per second. At this time, the higher-order frequencies are of little practical significance.

It should be noted further that the definition of \( \beta_z \) given in Equation (29) above is only an approximation, known as the Dehmelt approximation after Hans Dehmelt who shared the 1989 Nobel Prize in Physics along with Norman Ramsey and Wolfgang Paul; \( \beta_u \) is defined precisely by a continued fraction expression in terms of \( a_u \) and \( q_u \), as shown in Equation (30)

\[ \beta^2_{u} = a_u + (q_u^2) \left( \beta_u + 2 \right)^2 - a_u - (q_u^2) \left( \beta_u + 4 \right)^2 
- a_u - (q_u^2) / (\beta_u + 6)^2 - a_u - \cdots \]  

(30)

The resemblance of the simulated ion trajectory shown in Figure 6 to a roller coaster ride is due to the motion of an ion on the potential surface shown in Figure 3. The oscillatory motion of the ion results from the undulations of the potential surface that can be envisaged as rotation of the potential surface. The simulation of the ion trajectory was carried out using the ITSIM (ion trajectory simulation program),\(^{(17)}\) while the potential surface was generated\(^{(18)}\) from Equation (24) by calculating \( \phi_{r,z} \) for \( C_2^0 = 1 \) and all of the other coefficients equal to zero for increment steps of 1 mm in both radial and axial directions.

8 RESONANT EXCITATION

As the motion of ions confined in a quadrupole ion trap is characterized by two secular frequencies, axial and radial, ion motion can be excited upon resonant irradiation at either or both of these frequencies. Such irradiation can be effected by applying a small supplementary oscillating potential of some hundreds of millivolts across the end-cap electrodes, that is, in dipolar mode. Resonant excitation, using the axial secular frequencies of confined ions, has become a powerful technique in quadrupole ion trap MS due to the utilization of predetermined waveforms composed of specified frequencies or frequency ranges. Prior to resonant excitation of ion trajectories, ions are focused collisionally to the vicinity of the center of the ion trap under the influence of collisions with helium buffer gas atoms. This process is described as “ion cooling” in that ion kinetic energies are reduced to ca. 0.1 eV, corresponding to ca. 800 K as calculated from \( 3RT/2 = 0.1 \text{ eV} \). Ion excursions from the center of the ion trap are less than 1 mm.

Resonant excitation of cooled ions, brought about by a supplementary potential oscillating at the axial secular frequency of a specific ion species and of amplitude but a few hundreds of millivolts, causes those ions to move away from the ion trap center in such a way that they experience a greater trapping field. This process of ion excitation is often referred to as “tickling”. The ions are accelerated further by the trapping field so that they can achieve kinetic energies of tens of electron volts.

Resonant excitation is used in the following ways:

1. to remove unwanted ions during ionization so as to isolate a narrow range of mass/charge ratios; in this case, wavebands of frequencies are applied to

\[ \begin{aligned}
+ (q_u^2) & \left( (\beta_u + 2)^2 - a_u - (q_u^2) \right) \\
- a_u - (q_u^2) / (\beta_u + 6)^2 - a_u - \cdots 
\end{aligned} \]
the end-cap electrodes to excite and eject many ion species simultaneously leaving a single ion species (or a small range of mass/charge ratios) isolated within the ion trap;

2. to increase ion kinetic energy so as to promote endothermic ion/molecule reactions;

3. to increase ion kinetic energy so as to deposit internal energy in ions through momentum-exchange collisions with helium atoms; in the limit, ions dissociate. This mode of resonant excitation is discussed in more detail in section 10.2 on CID;

4. to increase kinetic energy so as to move ions close to an end-cap electrode where an image current can be detected. This mode permits the nondestructive measurement and remeasurement of the mass/charge ratio of confined ions;

5. to increase kinetic energy so as to cause ions to escape from the trapping potential and be ejected. This mode can be used either to eject unwanted ions, as in ion isolation, or to eject ions mass selectively while the applied frequency is swept;

6. to eject ions while the amplitude \( V \) of the main rf potential is being ramped up. This mode, known as axial modulation, is used in conjunction with an rf ramp so that ions come into resonance with a fixed frequency of ca. 6 \( V_{(p-p)} \) (peak-to-peak) just before their trajectories are made unstable. In this case, ions of low mass/charge ratio are removed from the perturbing influences of ions of higher mass/charge ratio and are detected with enhanced resolution.

In axial modulation, the resonant frequency is just less than half the main drive frequency \( \Omega \). Resonant excitation at lower frequencies has been used with great success to extend the normal mass range of the ion trap.

9 CALCULATIONS

On many occasions while working with a quadrupole ion trap it becomes necessary to calculate some of the ion trapping parameters such as \( q_z \), LMCO value (see below), \( \beta_z \), the secular frequency \( \omega_z \), and the potential well depth \( D_z \). In modern ion trap instruments, these calculations can be carried out using the accompanying software but it is instructive to examine the manner in which each of the following parameters is calculated.

Let us consider an ion of butylbenzene (\( m/z 134 \)) in a normal stretched ion trap which has a ring electrode of radius \( r_0 = 1.00 \) cm and with \( z_0 = 0.783 \) cm (corresponding to an electrode spacing, \( 2z_0 \), of 15.66 mm) and under the following conditions:

\[
U = 0; \quad V = 757 V_{(0-p)} \text{ at } 1.05 \text{ MHz}
\]

\[
\Omega = 2\pi f = 2\pi \times 1.05 \times 10^6 \text{ rad s}^{-1}
\]

\[
m = \frac{134 \text{ Da}}{\text{Avogadro’s number}} = 134 \times 10^{-3} \text{ kg mol}^{-1} \times 6.022 \times 10^{23} \text{ mol}^{-1}
\]

9.1 \( q_z \) and Low-mass Cut-off

From Equation (26), we recall that

\[
q_z = \frac{8eV}{m(r_0^2 + 2z_0^2)\Omega^2} \tag{26}
\]

Thus

\[
q_z = \frac{8(1.602 \times 10^{-19} \text{ C})(757 \text{ kg m}^{-2} \text{ s}^{-2} \text{ C}^{-1})}{(6.022 \times 10^{23} \text{ mol}^{-1}) \times (134 \times 10^{-3} \text{ kg mol}^{-1}) \times (1.000 + 1.226 \times 10^{-4} \text{ m}^2) \times (2\pi \times 1.05 \times 10^6 \text{ s}^{-1})^2}
\]

\[
eq 0.450
\]

We have now calculated that \( m/z 134 \) has a \( q_z \) value of 0.450 under these conditions, but what is the LMCO value at \( q_z \) slightly less than 0.908? Since \( m \times q_z = \text{constant} \) at constant \( V \) from Equation (26), the LMCO value can be calculated as:

\[
(\text{LMCO})(0.908) = (m/z 134)(0.450)
\]

Rearranging,

\[
\text{LMCO} = (m/z 134)(0.450)/(0.908)
\]

\[
= m/z 66.4
\]

That is, with a potential of 757 \( V_{(0-p)} \) applied to the ring electrode, only those ions of \( m/z > 66.4 \) will be stored. The potential \( V \) to be applied to the ring electrode to effect a given LMCO is given as

\[
V = (\text{LMCO}) \times (757 V_{(0-p)})/(m/z 66.4)
\]

\[
= (11.40 \times \text{LMCO})V_{(0-p)}
\]

This calculation is particularly useful when an ion is to be fragmented and one wishes to know the low mass/charge limit for fragment ions stored, that is, the LMCO.

9.2 \( \beta_z \)

From Equation (29), we see that \( \beta_z \) is given approximately by \( \sqrt{(q_z^2/2)} \) thus, when \( q_z = 0.450, \beta_z = 0.318 \). However, we have exceeded the limit of the approximation relating
$q_z$ and $\beta_z$ and so the calculated value of $\beta_z$ is high by about 5%. For $m/z$ 1340, where $q_z = 0.0450$ such that the above approximation is valid, the value of $\beta_z = 0.0318$.

9.3 $\omega_z$

From Equation (27), the fundamental axial secular frequency, $w_z$, (or, more properly, $w_{z,0}$) is given by $\beta_z \Omega_2$ thus, when $\beta_z = 0.318$ and $\Omega = 2\pi \times 1.05 \times 10^6 \text{ rad s}^{-1}$, $w_z = 1.049 \times 10^6 \text{ rad s}^{-1}$ or, more conventionally, $w_z = 167 \text{ kHz}$; $w_z$ is correspondingly high by about 5%. However, for $m/z$ 1340, $w_z$ is 16.7 kHz.

9.4 Mass Range

The upper limit of the mass range is given by the mass/charge ratio having a $q_z$ value of, let us say, exactly 0.900 when the maximum rf amplitude is applied to the ring electrode. From Equation (26) it is seen that $m \times q_z/V = \text{constant}$; this constant can be evaluated from the above expression for $q_z$ as 0.0797. With $q_z = 0.900$ and $V = 7340 V_{(0-p)}$, the mass range is found to be 650 Da.

9.5 Mass Range Extension

With $V = 7340 V_{(0-p)}$ and ion ejection brought about by axial modulation at, say, $q_z = 0.900$, the upper mass limit of the ion trap is 650 Da; that is, for $m/z$ 650, $q_z = 0.900$. However, under these trapping conditions, ions of $m/z$ 1300 remain stored in the ion trap and have a $q_z$ value of 0.450. If resonant excitation had been carried out at $q_z = 0.45$ with excitation at 167 kHz (see above), ions of $m/z$ 1300 would be on the point of ejection at the maximum rf amplitude and the mass range of the ion trap would have been doubled to 1300 Da. Similarly, with resonant excitation at $q_z = 0.045$, the mass range would be extended to 13000 Da. This method has been applied\(^{(19)}\) with great success, using axial modulation at low $q_z$ and a slightly lower drive frequency $\Omega$, such that the mass/charge range was extended to 72000 Da per charge.

9.6 Mass Resolution

The normal mass scan rate of Finnigan and Varian ion traps prior to 1995 was 5555 Da s\(^{-1}\) and over the normal mass range of 10-650 Da, peak width was maintained at ca. 0.5 Da. Mass resolution is defined as the ratio of the mass of an ion to the peak width at half height; hence mass resolution increases with mass. However this statement is somewhat misleading as can be seen from the following example: mass resolution for $m/z$ 65 is ca. 130 while that for $m/z$ 650 is 1300. The real performance of the instrument is gauged from the width of the ion signals produced upon ion ejection. Upon reducing the scan rate, it was observed\(^{(20)}\) that the peak width was reduced so that for a given mass, mass resolution was increased. While in research instruments peak widths of some 20 µDa have been observed, the narrowest peak widths in commercial instruments are ca. 0.2 Da so that, for $m/z$ 2000, a mass resolution approaching 10,000 is achieved.

9.7 $D_z$

The essential importance of the potential well depth is that it determines both the minimum kinetic energy that an ion must acquire by resonant excitation in order to be ejected from the ion trap and the maximum kinetic energy that an externally generated ion may possess and still be trapped. The magnitude of the potential well in the z-direction may be estimated from the approximation that $D_z \approx q_z V/8$ thus, for our example of $m/z$ 134 at $q_z = 0.450$, $D_z \approx 0.45 \times 757 V/8 = 43 V$.

10 MASS SPECTROMETRIC OPERATION OF THE QUADRUPOLE ION TRAP

A schematic diagram of the QITMS is shown in Figure 11. This figure does not show the end of the gas chromatograph capillary column from which elutes the sample of interest in the helium carrier gas. The gate control in Figure 11 permits the passage of a 200-µs burst of electrons from the filament for automatic gain control (AGC). The fundamental rf voltage is ramped rapidly to eject ions formed during the brief burst of electrons. Under AGC, the instrument calculates the duration of ionization appropriate to the stipulated ion count and the prevailing partial pressure of sample in the ion trap. All forms of resonant excitation are effected with the supplementary AC voltage applied to the end-cap electrodes as shown in Figure 11. When this supplementary AC voltage is used for axial modulation, ions are ejected in order of mass/charge ratio, impinge upon the electron multiplier detector, and produce a signal after preamplification. All

![Figure 11 Schematic diagram of the QITMS.](image-url)
The pressure of helium in the ion trap is set at about ca. 400 µg of dioxin dissolved in 2 µL of n-nonane is used. The pressure of helium in the ion trap is set at about 10⁻³ Torr to provide adequate cooling of ions formed; while helium can be used directly from a cylinder, the helium carrier gas flowing through a chromatograph provides an adequate background pressure in the ion trap.

Dioxin (2,3,7,8-tetrachlorodibenzo-p-dioxin T₄CDD) is used for illustrating the use of the ion trap as a MS; dioxin is an excellent example of the application of ion trap MS to analytical chemistry. Compounds such as dioxin are analyzed from complex mixtures where they are present in trace amounts and, under such circumstances, gas chromatography (GC) is a common method for sample introduction; in this example, ca. 400 µg of dioxin dissolved in 2 µL of n-nonane is used. The pressure of helium in the ion trap is set at about 10⁻³ Torr to provide adequate cooling of ions formed; while helium can be used directly from a cylinder, the helium carrier gas flowing through a chromatograph provides an adequate background pressure in the ion trap.

Dioxin molecules elute directly into the ion trap where they are bombarded with electrons of 50–80 eV emitted from a heated filament and gated into the ion trap, as shown in Figure 11. The duration of ionization is determined by AGC; the ion number formed during an ionization burst is used to scale the ionization time in order to produce the required number of ions. The ions thus formed come immediately under the influence of the trapping potential within the ion trap. During ionization, the ring electrode is driven at an initial rf voltage \( V_0 \) and a fixed frequency \( f \approx 1 \text{ MHz} \) so that the confining field is purely oscillatory. During and after ionization, ions follow Lissajous-type trajectories and are subjected simultaneously to about 20 000 collisions per second with helium; those ions that are not lost from the ion trap become focused near the trap center. The rf amplitude is ramped during the analytical scan and as the axial secular frequency of ion motion comes into resonance with the axial modulation frequency, mass-selective ion ejection and mass analysis occur.

Each ion species confined within the ion trap is associated with a \( q_z \) value which is calculated according to Equation (26) and which lies on the \( q_z \)-axis on the stability diagram; ions of relatively high mass/charge ratio have \( q_z \) values near the origin while ions of lower mass/charge ratio have \( q_z \) values which extend towards 0.908, the ions are ejected axially through the end-cap electrodes. This method of ion ejection, which is referred to as mass-selective axial instability, has been supplanted by the use of axial modulation. Originally, axial modulation was the name given to resonant ejection of ions at a frequency of 485 kHz and at a \( q_z \) value only slightly less than 0.908.

Once the ion cloud within the ion trap has been focused collisionally to the center of the ion trap over a period of some 1–30 ms, the amplitude of the rf potential is ramped. The ramping of the rf potential amplitude, which is described as an analytical ramp or analytical scan, causes the \( q_z \) values of all ion species to increase throughout the ramp. As the \( q_z \) value for each ion species reaches a value of 0.908, the ions are ejected axially through the end-cap electrodes. This method of ion ejection, which can occur only at a boundary of the stability diagram and is referred to as mass-selective axial instability, has been supplanted by the use of axial modulation. Originally, axial modulation was the name given to resonant ejection of ions at a frequency of 485 kHz and at a \( q_z \) value only slightly less than 0.908.

When the rf amplitude is ramped, ions come into resonance at 485 kHz as their \( q_z \) values approach 0.908; in this manner, ions are ejected axially in order of increasing mass/charge ratio. As ions are focused into a region at the center of the ion trap, they are arranged in concentric layers rather than the fashion of an onion. Resonance ejection affects first the ions of low mass/charge ratio residing in the innermost layer of the onion by removing them axially from ions of higher mass/charge ratio. In this manner, the influence of space charge perturbations induced by the ion of higher mass/charge ratio is sharply
reduced so that the ions of low mass/charge ratio are ejected free of space charge and with enhanced mass resolution. An additional advantage of resonant ejection is that it can be carried out at any frequency. Resonant ejection is depicted pictorially in Figure 12(b) where ions are shown residing near the bottom of their respective axial potential wells of depth $D_z$; the ladder represents the opportunity for resonant ejection of an ion species at any frequency. For axial modulation, the ladder is positioned at a $q_z$ value just a little less than 0.908. Resonantly ejected ions pass through holes in the end-cap electrodes so that only half of them impinge upon an electron multiplier located behind one of the end-cap electrodes; ion signals are created which produce a mass spectrum in order of increasing mass/charge ratio. The quadrupole ion trap functions as a mass spectrometer when operated in this manner.

A mass spectrum is obtained by running the scan function (see below) a number of times specified by the number of microscans; the signals which compose the mass spectrum are the result of averaging those obtained from each microscan. In the following example of obtaining a mass spectrum, a mass spectral file was generated each second. A mass spectrum of 2,3,7,8-T₄CDD obtained in this manner is shown in Figure 13. M⁺⁺ is of $m/z$ 320 and the [M + 2]⁺⁺ ion of the molecular cluster which is shown at $m/z$ 322 corresponds to the inclusion of one $^{37}$Cl atom; the ion of $m/z$ 259 is a primary fragment ion and is due to the loss of COCl⁺ from [M + 2]⁺⁺ and of CO$^{37}$Cl⁺ from [M + 4]⁺⁺. The peak at $m/z$ 334 is [M + 2]⁺⁺ from a relatively small amount of $^{13}$C-labeled $^{13}$C₁₂-2,3,7,8-T₄CDD, M⁺⁺ of $m/z$ 332, added to the sample injected.

10.1 Scan Function

The sequence of events described above can be expressed succinctly in a scan function which shows the temporal variation of all of the potentials applied to the ion trap electrodes. A scan function is a visual representation of the sequence of program segments in the software that controls ion trap operation. The scan function for the mass spectrometric operation of the ion trap described above is shown in Figure 14.

10.2 Collision-induced Dissociation

CID of an isolated ion species in a quadrupole ion trap has become a powerful technique for both the determination of ion structures and the analytical determination of, for example, compounds of environmental interest such as dioxin. Before we explore each of these uses, let us consider the CID process, how ion dissociation is effected, the efficiency of the process, and the duration.

While CID is effected by resonant excitation of a selected ion species in the ion trap, the process is made more complex since the frequencies of ion motion change slightly as an ion moves away from the ion trap center; the values of the frequencies of ion motion are dependent also on space charge, that is, on the number and nature of other ions present in the ion trap. The variation in axial frequency with axial excursion, which is shown in

![Figure 13](image-url)  
*Figure 13* Mass spectrum of 2,3,7,8-T₄CDD. The [M + 2]⁺⁺ ion of the molecular cluster is shown at $m/z$ 322, while that of a trace of $^{13}$C₁₂-2,3,7,8-T₄CDD is shown at $m/z$ 334; the primary fragmentation process is the loss of COCl⁺ giving rise to $m/z$ 259 and 270, respectively.
Figure 14 Scan function for obtaining an EI (electron ionization) mass spectrum. The scan function shows the ionization period, $A$, followed immediately by the analytical ramp with concurrent axial modulation. Note that the prescan for the AGC algorithm is not shown.

Figure 15 Variation of ion axial secular frequency as a function of the axial excursion from the center of the ion trap. Ion trajectories were calculated for three $m/z$ 134 ions, 1 (●), 2(●) and 3(●), taken at random, with $q_z = 0.4$ and subjected to resonant excitation. While the three ions differed in their initial position and velocity, all were close to the center of the ion trap and had been cooled collisionally. When specific axial excursions had been reached, ion excitation was arrested and the trajectory of each ion was subjected to frequency analysis.

Figure 15 as obtained from analysis of simulated ion trajectories, arises from the superimposition of higher order field components as a result of the axial “stretching” of the ion trap.$^{21,22}$ The secular frequency variation necessitates the development of strategies for optimizing CID, particularly when the duration of irradiation must be minimized as in GC/MS (gas chromatography/mass spectrometry) analytical applications; these strategies include secular frequency modulation, single frequency irradiation with rf modulation, and multiple frequency irradiation.

Under the influence of the applied resonant excitation voltage, ions are moved away from the center to a region of higher potential whereupon they are accelerated (under the influence of the higher potential rather than the resonant excitation voltage alone) so that their kinetic energies are increased. Subsequent collisions with buffer gas atoms lead to enhancement of ion internal energy. Ions undergo rapid changes in kinetic energy on the microsecond timescale whereas changes in internal energy occur more slowly on the millisecond timescale. In analytical applications, the objective is usually to dissociate all of the isolated ions and to maximize the trapping of fragment ions produced; the achievement of this objective requires a balancing of ion kinetic energy uptake so that ion internal energy may be accumulated incrementally and rapidly but ejection of both isolated ions and fragment ions is prevented. Incremental loss of internal energy in collisions can occur with both buffer gas atoms and sample molecules while total loss of internal energy can occur upon charge exchange with sample molecules; yet these loss mechanisms merely slow down the overall accumulation of internal energy as there is no net loss of charge involved.

The role played by time is enormously important in CID. The total time during which ions are subjected to collisions and the total time during which ions are subjected to irradiation can be used as variable parameters to direct dissociation into a chosen fragmentation pathway. While the mode of irradiation is also influential in directing fragmentation, alternating periods of irradiation (with collisions) and collisional cooling can affect significantly the fragment ion abundances. During an irradiation period, the time-averaged ion kinetic energies increase along with internal energy; during a subsequent collisional cooling period in which the excitation voltage is removed, ion kinetic energies are quenched more readily than are ion internal energies. Thus ions become kinetically relaxed during a cooling period and sample once more the lower reaches of the trapping potential well, yet the internal energies gained are virtually unimpaired. The internally excited ions, kinetically cool and focused near the center of the ion trap, can be excited further during the next irradiation period. In this manner, several electron volts of internal energy can be deposited in ions to allow access to fragmentation pathways of high activation energy.
11 TANDEM MASS SPECTROMETRY

Tandem (Latin: at length) mass spectrometry, (MS/MS) or (MS)n, is the practice of carrying out one mass-selective operation after another, much as one rider is seated after the other on a tandem bicycle. The objective of the first mass-selective operation is to isolate an ion species designated as the parent ion, while that of the second operation is to determine the mass/charge ratios of the fragment, or product, ions formed by CID of the parent ions. MS/MS can be effected in space, by placing one mass spectrometer after another, or by carrying out successive mass-selective operations in time in a quadrupole ion trap. The ion trap offers two principal advantages when used in the MS/MS mode. First, the ion trap operates in a pulsed mode, compared with sector and triple stage quadrupole instruments that operate in a continuous mode, so that it can accumulate ions mass-selectively over time. In this way, a target ion number can be selected so as to ensure constant signal/noise ratio over a wide range of eluent concentrations. A disadvantage of ion accumulation is that the resultant product ion signal intensity can correspond to integration of eluent concentration over some 25 ms. Second, CID in the ion trap is wrought by some hundreds of collisions of mass-selected ions with helium buffer gas atoms. Under these conditions, the energy transferred in a single collision is seldom greater than that of a vibrational quantum such that the dissociation reaction channels of lowest energy of activation are accessed almost exclusively; this behavior is highly advantageous in analytical chemistry because the total charge is conserved within a single fragment ion species. However, alternating periods of excitation and collisional cooling can be used to allow access to dissociation reaction channels of higher energy of activation. Furthermore, it is possible to dissociate completely the accumulated mass-selected ions and to confine within the ion trap fragment ions arising from some 90% of the accumulated mass-selected ions in favorable cases.

To achieve CID with such high efficiency (defined as 100 times the ratio of the sum of product ion signal intensities to that of the parent ion) when the ion trap is interfaced with a gas chromatograph, it is imperative that the resonant excitation conditions be optimized with respect to the duration of the CID episode. Here, we use multifrequency irradiation (MFI) as it has been shown to be an effective method for CID because it exhibits high efficiency and requires a relatively short period of irradiation, ca. 10 ms.

11.1 Tandem Mass Spectrometry

Here, MS/MS is illustrated using an extension of the dioxin example used in the above discussion. This application, while not illustrating the ultimate limit of sensitivity of the ion trap of some hundreds of

![Figure 16](image_url)

Figure 16 Scan function for MS/MS of dioxin T4CDD; the prescan for AGC is not shown.
femtograms of dioxin, does illustrate the high sensitivity of the ion trap for the determination of co-eluting dioxin congeners. Polychlorodibenzo-p-dioxins (PCDDs) and polychlorodibenzofurans (PCDFs) are persistent organochlorine compounds in the environment; most of these chlorocongeners are obtained from municipal and industrial waste incinerators, automobile exhaust, and the manufacture of chlorophenol products. The compounds having the highest toxicity have been identified as those congeners having 2,3,7,8-tetrachloro-substitution. When GC is interfaced with MS, individual chlorocongeners can be detected at the hundreds of femtograms level. The high specificity or informing power obtainable with GC/MS/MS is achieved by observation of specific fragment ion signals, such as \([M - COCl]^{+}\), from an isolated ion species \(M^{+}\) formed from \(M\) which elutes within a specified retention-time window. The essential stages of MS/MS are portrayed in the scan function for dioxin shown in Figure 16. It is instructive to examine this scan function in advance of the following explanation of ionization, ion isolation, cooling period, CID, and the analytical ramp over a selected mass range so as to detect product ions.

We shall examine the MS/MS of \([M]^{+*}\) and \([M + 2]^{+*}\) for T4CDF (tetrachlorodibenzofurans), T4CDD and their internal (labeled) standards following elution from a GC column, where \([M + 2]^{+*}\) is a molecular ion containing a single \(^{37}\text{Cl}\) atom.

11.2 Scan Functions

The scan function employed for the MS/MS determination of T4CDDs is shown in Figure 16. The rf voltage is applied to the ring electrode with a drive frequency \(f\) of 1.05 MHz. The LMCO value, as determined by the amplitude of the rf potential, was set at \(m/z\) 160 during the ionization period (A) for all the scan functions so that the \(q_z\) value for \(M^{+*} (m/z\) 320) was 0.45. While the same scan function can be used for all T4CDDs, as they do not co-elute, different scan functions must be used in sequence for the determination of a specific T4CDD and its co-eluting labeled isotopomer.

A total ion number target of 35 000 counts was set for the AGC algorithm; with a filament emission current of 50 \(\mu\)A, the maximum ionization time employed was 20 ms. The supplementary alternating voltages applied to the end-cap electrodes in dipolar fashion are referred to as waveforms; these waveforms are employed for ion isolation, ion excitation, and axial modulation. A preisolation waveform was imposed during ionization (A) and prolonged after the cessation of ionization during period B. The pre-isolation waveform consisted of multiple frequencies covering the range 3.7–513.5 kHz with a 1 kHz notch corresponding to the secular frequency of the molecular ions to be isolated. For the example of a T4CDD scan function shown in Figure 16, the notch is centered at 174.5 kHz in order to isolate both \(m/z\) values.
320 and m/z 322, [M]⁺⁺ and [M + 2]⁺⁺, respectively, having \( q_z \) values of 0.454 and 0.451, respectively. The amplitude of the pre-isolation waveform was 20 \( V_{(0-p)} \) for all scan functions; the function of the pre-isolation waveform was to eject all ions except those within a mass range of ca. 10 \( Da \) about the selected ones. Fine isolation was achieved by ramping the rf amplitude until the LMCO was just less than m/z 320 at which point ions of lower mass/charge ratios were ejected; ejection of ions of higher mass/charge ratio was facilitated by concurrent application of axial modulation with an amplitude of 3 \( V_{(0-p)} \). The rf amplitude was modulated over a small amplitude range in order to avoid ejection of the selected ions. The ejection of ions with m/z > 322 (C) was achieved by applying a broad band waveform having an amplitude of 30 \( V_{(0-p)} \) and lasting for 5 ms.

Once isolation of the selected ion species m/z 320 and m/z 322 for T₄CDF as illustrated in Figure 17(a) was completed, the rf amplitude was reduced to obtain a qₑ value of 0.4 for m/z 322; for T₄CDD, a qₑ value of 0.4 for m/z 322 corresponds to a LMCO value of m/z 142. The bandwidth of the waveform employed to carry out CID using MFI was composed of 13 frequency components spaced at intervals of 0.5 kHz so as to cover a 6 kHz band of frequencies. The total bandwidth is almost double the required bandwidth since the Toolkit® software locks the center of the MFI band to the axial secular frequency of the previously selected ion species; only the width of the MFI band can be varied. The MFI waveform amplitudes were 2.55 \( V_{(0-p)} \) for T₄CDF and 2.45 \( V_{(0-p)} \) for T₄CDD. The voltage amplitude of each component of the MFI waveform is equal to the amplitude of the waveform divided by the number of frequency components. The rf amplitude was modulated so as to cover completely the frequency range of the 13 frequency components of MFI.

Following CID by MFI for 10 ms, the analytical mass range of 165–350 \( Da \) was scanned for product ions from T₄CDF and T₄CDD so as to monitor all major product ions save that resulting from chlorine atom loss. A mass spectrum of the product ions from dioxin is shown in Figure 17(b); m/z 257 and m/z 194 are due to the losses of COCl⁺ or 2COCl⁺, respectively, from M⁺⁺ (m/z 320). The analytical ramp was scanned at 5555 \( Da s^{-1} \); axial modulation was carried out with an amplitude of 3 \( V_{(0-p)} \) and at a frequency of 485 kHz. The electron multiplier was biased at a voltage of ca. 1800 \( V \) to provide an ion signal gain of \( 10^6 \).

Each scan function used had a duration of ca. 125 ms such that each acquisition point or mass spectral file was generated from four microscans; thus two mass spectra were accumulated each second. It should be noted that when a small mass range only is monitored during the analytical rf ramp, say for two fragment ions only, the duration of the scan function can be reduced to only 50 ms; in this case, the number of mass spectral files can be increased to five per second, each based on four microscans. The mass spectra obtained from the application of each scan function within an ion preparation file were merged together to form a single merged mass spectrum. The significance of this merging procedure is described below.

### 11.3 Tandem Mass Spectrometry Determination of Eluting and Co-eluting Compounds

The total ion chromatogram shown in Figure 18 was obtained by GC/MS/MS of 1 \( \mu L \) of solution containing 200 \( pg \) of each of a T₄CDF, a \(^{13}C_{12}-T₄CDF\), a T₄CDD and a \(^{37}Cl₄-T₄CDD\) and 100 \( pg \) of each of two \(^{13}C_{12}-T₄CDDS\). The peak indicated with an asterisk in Figure 18 is an impurity present in the sample. This chromatogram is described more properly as a merged total ion chromatogram since it is a display of the total ion count of each merged mass spectrum obtained as described above.

Let us consider the first three peaks of interest which were observed in this merged total ion chromatogram, that is, those peaks labeled 1, 2 and 3. Peak 1 is due to a T₄CDF and its co-eluting \(^{13}C_{12}-labeled\) isotopomer (a component of the solution injected); peak 2 is due solely to a \(^{13}C_{12}-T₄CDD\) while peak 3 is a composite peak of a native T₄CDD and its \(^{13}C_{12}-\) and \(^{37}Cl₄\) labeled isotopomers.

For the T₄CDF of molecular weight is 304, the molecular ion M⁺⁺ of m/z 304 and the [M + 2]⁺⁺ of m/z 306 were isolated simultaneously then dissociated collisionally using MFI in accordance with a specific scan function. The signal intensities of fragment ions formed by the loss of COCl⁺ or CO\(^{37}Cl⁺\) to yield m/z

![Figure 18](image-url)
241 and m/z 243 were recorded, summed and shown in Figure 19. For MS/MS of the co-eluting $^{13}$C$_{12}$-T$_4$CDF, the second scan function comes into play for the ionization and simultaneous isolation of both M$^{* *}$ of m/z 316 and [M + 2]$^{* *}$ of m/z 318; the isolated ion species were then subjected to CID with MFI. The signal intensities of fragment ions formed by the loss of COCl$^*$ or CO$^{37}$Cl$^*$ to yield m/z 252 and m/z 254 were recorded and summed as shown in Figure 19. Throughout the period when the native and labeled T$_4$CDFs are co-eluting, the first two scan functions are used alternately.

Now let us consider peak 2 of Figure 18. A third scan function is required for the MS/MS determination of the labeled $^{13}$C$_{12}$-T$_4$CDD to control the ionization, isolation, and CID of both the molecular ion M$^{* *}$ of m/z 332 and the [M + 2]$^{* *}$ of m/z 334. The signal intensities of fragment ions formed by the loss of COCl$^*$ or CO$^{37}$Cl$^*$ to yield m/z 268 and m/z 270 were summed and recorded in Figure 19.

Peak 3 of Figure 18 is composed of the fragment ion counts from three compounds. The scan function used in peak 2 was used again for the MS/MS determination of a T$_4$CDD together with two additional scan functions for the co-eluting $^{13}$C$_{12}$- and $^{37}$Cl$_4$-T$_4$CDF isotopomers. For T$_4$CDD of molecular weight 320, the molecular ions M$^{* *}$, of m/z 320, and [M + 2]$^{* *}$, of m/z 322, were isolated simultaneously then were dissociated as before; the resulting signal intensities of the fragment ions of m/z 257 and m/z 259, as shown in Figure 17, were summed and recorded in Figure 19. From the MS/MS of the $^{13}$C$_{12}$-T$_4$CDF, the signal intensities of the fragment ions of m/z 268 and m/z 270 were summed and recorded in Figure 19. For the MS/MS of $^{37}$Cl$_4$-T$_4$CDD of molecular weight 328, the molecular ion M$^{* *}$ of m/z 328 was isolated then dissociated as before and the signal intensity of the fragment ions arising from the loss of CO$^{37}$Cl$^*$ to yield m/z 263 was recorded in Figure 19.

The signal areas of each of the six separated compounds are shown in Figure 19 as selected ion chromatograms; the signal intensities of fragment ions due to loss of COCl$^*$ or CO$^{37}$Cl$^*$ are plotted here. In order to perform MS/MS on the total of six different tetrachlorinated dioxins and furans which constituted the first three peaks of Figure 18, a total of five different scan functions was required. In this example, the enormous power of MS/MS is evident in the determination of three co-eluting compounds.

In the above discussion, only a single fragmentation channel was considered, that of the loss of COCl$^*$ or CO$^{37}$Cl$^*$. While COCl$^*$ loss is the major fragmentation channel, it is not the sole loss channel. For the dioxins, minor losses of Cl$^*$ and 2COCl$^*$ are observed while for the furans, minor losses of Cl$^*$, COCl$^*$ and COCl$_2$ are observed. The duration of the analytical rf ramp was reduced by selecting a small mass range that excluded the fragment ions of low intensity.

11.4 Tandem Mass Spectrometric Operation

The above sequence of ion isolation and CID can be repeated many times in a process known as (MS)$^n$. While this process is not illustrated here, multiple stages of mass-selective operation are used frequently for ion structure determination where the quadrupole ion trap is used
in combination with external ionization sources, such as ESI. Here, multiply charged molecules having masses of thousands of daltons can be stored in an ion trap and subjected to (MS)^n so as to follow the stepwise ion dissociation for the elucidation of ion structure.

12 CHEMICAL IONIZATION AND ION/MOLECULE REACTIONS

In the quadrupole ion trap, several types of reactions can and do occur simultaneously and spontaneously once EI of a compound has occurred. Ion/molecule reactions involving charge transfer, proton transfer, and clustering occur sequentially in a type of thermodynamic “waterfall” which results in the formation of stable even-electron ions of greater mass/charge ratio than that of the molecular ion. Proton transfer CI, involves the transfer to a neutral species of a proton from an ion which has been formed in an ion/molecule reaction. Parenthetically, CI can be effected by the transfer of other even-electron charged particles.

Let us consider the CI of the co-eluting PCB congeners 77 and 110 shown in Scheme 1. Congener 77, which is highly toxic, is a nonortho compound because the molecule is not chlorine-substituted in the ortho positions vicinal to the phenyl–phenyl bond. On the other hand, congener 110 is a diortho compound and is much less toxic. Since the concentration of toxic congener 77 in environmental samples is often <1% of that of congener 110, quantitative analysis of congener 77 is a challenge.

The EI mass spectrum, averaged over the GC composite peak of the co-eluting congeners 77 and 110, is shown in Figure 20. The base peak group in the mass spectrum is the molecular ion cluster of the tetrachloro-congener 77, where m/z 292 is [M + 2]^+; this peak is superimposed on the fragment ion cluster owing to the loss of one chlorine atom from pentachloro congener 110 [M + 2]^+, m/z 326, where m/z 291 is [M + 2 – Cl]^+. The peak at m/z 220 is due to loss of 2Cl^+ from [M + 2]^+ and 3Cl^+ from [M + 2]^+, while the peak at m/z 256 is due principally to the loss of 2Cl^+ from [M + 2]^+. It is not possible to determine quantitatively the relative contributions of the two congeners to this mass spectrum. Now let us examine the CI of these congeners using methane as the CI reagent.

The ionization of methane yields the molecular ion that reacts with methane to form CH₅^+. Equation (31)

\[
\text{CH}_4^{+} + \text{CH}_4 \rightarrow \text{CH}_5^{+} + \text{CH}_3
\]  

(31)
and the CH$_3^+$ ion which reacts with methane to form C$_2$H$_5^+$, Equation (32)

\[
\text{CH}_3^+ + \text{CH}_4 \rightarrow \text{C}_2\text{H}_5^+ + \text{H}_2 \quad (32)
\]

In practice, an LMCO of ca. $m/z$ 12 is established by the rf amplitude then methane is introduced briefly into the ion trap and ionized simultaneously with the congeners. Owing to the preponderance of methane, CH$_3^+$ and C$_2$H$_5^+$ are formed rapidly during a short interval inserted into the scan function for ion/molecule reactions and can be isolated; during the isolation process, primary ions of methane and the congeners together with other secondary ions from methane are ejected and surplus methane is pumped away. Proton transfer then occurs during a reaction period of ca. 10 ms.

When methane is used as a CI reagent and the reaction time is varied such that the signal intensities of CH$_3^+$ and C$_2$H$_5^+$ are similar, CI of a mixture of congeners 77 and 110 yields a mixture of proton transfer CI (to form [M + H]$^+$) and charge transfer (to form M$^{++}$), as shown in Figure 21(a). However, when a single reagent ion
species, in this case C₂H₅⁺ of m/z 29, is isolated for CI, proton transfer only is observed for both congeners, ([M₇₇ + 2 + H]⁺, m/z 293 and [M₃₁ + 2 + H]⁺, m/z 327), as shown in Figure 21(b). The isotopic ratios for each cluster of protonated congeners are in good agreement with those expected for pure CI: the contribution of charge exchange to the congener 77 molecular cluster is 3%. The mass spectrum is entirely free of fragment ions below [M₇₇ + H]⁺. The adduct formation channel can be suppressed by reducing reagent gas pressure.

Now that external ion sources can be used with an ion trap, CI reagent ions can be created externally and injected subsequently into the ion trap, isolated mass selectively and allowed to react therein with sample molecules.

13 CONCLUSIONS

The QITMS is a versatile instrument of high sensitivity and high specificity. The relatively low cost of commercial instrumentation has permitted a substantial growth in the practice of MS and a pronounced diminution of the average cost per mass spectrum. The theory of ion trap operation differs from those of other mass spectrometers and presents a challenge to the MS community.

# Secondary Ion Mass Spectrometry as Related to Surface Analysis

Scott D. Hanton and Paula A. Cornelio Clark  
Air Products and Chemicals, Inc., Allentown, USA

## 1 Introduction

Many important processes such as catalysis, corrosion, and adhesion depend on the elemental and molecular composition of the surface or interfacial region. The focus of this article is specifically surface applications of secondary ion mass spectrometry (SIMS). Conceptually, SIMS is a very simple technique consisting of a primary ion bombardment step, an energy transfer step, a particle desorption step, and an ion detection step. SIMS experiments are carried out in either a dynamic or a static mode. The two modes are distinguished on the basis of ion dose. Dynamic SIMS uses high primary ion beam doses and is generally used for elemental depth profiling. Static SIMS uses low primary ion beam doses \((\leq 1 \times 10^{12} \text{ ions cm}^{-2})\) and is generally used for the chemical characterization of surfaces. The major advantages of SIMS include high sensitivity (parts per million detection limits for some elements), the ability to obtain molecular information, isotopic analysis, lateral characterization (imaging), and analysis of low-atomic-number elements such as H and Li. These characteristics combine to make SIMS a very powerful analytical tool. Related analytical techniques for surface analysis include X-ray photoelectron spectroscopy (XPS), Auger electron spectroscopy (AES), Scanning Auger Microscopy (SAM), and laser desorption mass spectrometry (LDMS).

## 1 INTRODUCTION

Many important processes, such as catalysis, corrosion, and adhesion, depend on the elemental and molecular composition of the surface or interfacial region. For example, the anticorrosive nature of 316L stainless steel is due to a 100 Å Cr-rich surface layer. Surface analysis can refer to a broad range of physical and spectroscopic techniques. Each of these techniques has advantages and disadvantages and it is significant to emphasize the power of a multitechnique approach in industrial problem solving. The focus of this article is specifically surface applications of SIMS. Conceptually, SIMS is a very simple technique consisting of a primary ion bombardment step, an energy transfer step, a particle desorption step, and an ion detection step. The major advantages of SIMS include high sensitivity (parts per million detection limits for some elements), the ability to obtain molecular information, isotopic analysis, lateral characterization (imaging), and analysis of low-atomic-number elements such as H and Li. These characteristics combine to make SIMS a very powerful analytical tool. Initially used as an ion microprobe technique, SIMS has played an important role in the semiconductor industry. Today, thanks to the pioneering efforts of Benninghoven,
Hercules, Briggs, and many others, SIMS is finding wide application in industrial polymer analysis.

2 SURFACE ANALYSIS

We must begin by answering three fundamental questions: what is a surface?; how deep is the surface region?; and why are surfaces technologically important?

What is a surface? From first principles, we know that the four states of matter in the universe are solid, liquid, gas, and plasma (ionic species). None of these phases is infinite. The region of a sample where one phase ends and another begins is called the surface phase or interfacial region. The possible boundaries can be gas–liquid, gas–solid, liquid–liquid, liquid–solid, and solid–solid.\(^{1–3}\)

How deep is the surface region? It takes work to bring a molecule from the interior of the material to the surface.\(^{3–5}\) This work is the surface free energy. The work arises from the fact that the molecule experiences an imbalance in forces as it moves to the surface. Note that a molecule in the bulk experiences no such imbalance in forces. The imbalance in forces results in “surface tension”.\(^{3}\) Surface tension can be thought of as the horizontal pull arising from the work to raise a molecule out of the bulk to the surface.

In the 1800s, Laplace postulated that the depth of the “unbalanced forces”, or the depth of the surface region, depends on short-range intermolecular forces.\(^{5}\) With the exclusion of ionic species, the principal forces between molecules are van der Waals forces. These forces decrease with about the seventh power of the intermolecular distance! Hence the interactions between nearest neighbors are the most important. A molecule experiences essentially symmetrical forces once it is a few molecular diameters away from the surface.

Why are surfaces technologically important? Many important processes, such as catalysis, corrosion, and adhesion, depend on the elemental and molecular composition of the interfacial region. For example, the anticorrosive nature of 316L stainless steel is due to an enrichment of Cr at the surface. The Cr to Fe ratio at the surface is about 2 : 1 compared with the bulk ratio of about 0.20 : 1, as measured by AES. This Cr-enriched layer is only about 100 Å (or 0.01 µm) thick.

Surface analysis can refer to a broad range of physical and spectroscopic methods. A summary of some of the commonly employed surface analytical methods are provided in Tables 1 and 2. Each of these techniques has advantages and disadvantages. Each also has a sampling depth or information depth. The sampling depth will determine how much of the surface is measured. The focus of this article is specifically surface applications of SIMS in the analysis of surfaces.

Figure 1 shows a schematic diagram of a typical SIMS experiment.

Conceptually, SIMS is a very simple technique consisting of a primary ion bombardment step, an energy transfer step, a particle desorption step, and an ion detection step. The sample (usually a solid) is introduced into an ultrahigh vacuum (UHV) chamber at pressure

b TOF, time-of-flight.

Figure 1 Schematic diagram of SIMS process.

≤1 × 10^{-9} Torr (1 Torr = 133.3 Pa). The sample is bombarded by a primary ion beam (typically Xe, Ar, Ga, or Cs ions) accelerated to 5–25 kV. The primary ion impacts the surface and penetrates about 100 Å into the sample. The impact of the primary ion results in an energy and momentum transfer process called the collision cascade. The energy and momentum transfer result in the desorption (sputtering) of neutral species, electrons, and secondary ions from the surface of the sample. The secondary ions are mass analyzed. The major advantages of SIMS include, high sensitivity (parts per million detection limits for some elements), the ability to obtain atomic and molecular information, isotopic analysis, lateral characterization (imaging), and analysis of low atomic number elements such as H and Li.

Secondary ion yields are strongly influenced by the chemical and electrical properties of the surface. Benninghoven showed that secondary ion yields for elements

2.1 Dynamic Secondary Ion Mass Spectrometry

In its early applications, SIMS was referred to as an ion probe technique and found applications in elemental compositional analysis. Detection limits in the parts per billion (ppb) range were achieved by using a high primary ion flux. The high primary ion flux also ensured the removal of a number of monolayers per second, making dynamic SIMS well suited for elemental depth profiling. Dynamic SIMS is an extremely valuable tool to the semiconductor industry.

Ideally, the number of ions sputtered from the sample should be linearly related to concentration, independent of the element, independent of the sample being analyzed, and independent of the primary bombarding species. Unfortunately, none of these conditions are met in SIMS. The linear dependence of signal is observed only for dilute systems, secondary ion yields vary greatly for different elements, secondary ion yields vary greatly for the same element in different matrices (matrix effects), and secondary ion yields depend upon the kinetic energy, size, and incident angle of the primary ion. Figure 2 illustrates the variation in secondary ion yields for various elements.

Secondary ion yields are strongly influenced by the chemical and electrical properties of the surface. Benninghoven showed that secondary ion yields for elements
sputtered from clean metal surfaces are significantly lower than those of the same elements sputtered from an oxidized surface.\textsuperscript{12}

In SIMS, one often observes significant variations in secondary ion intensity for a given element in different matrices. Figure 3(a–c) illustrate this matrix effect.\textsuperscript{9} Figure 3(a) shows the depth profile of Be in GaAs. Figure 3(b) shows a depth profile of Mg, and Figure 3(c) shows Be implanted through a Si\textsubscript{3}N\textsubscript{4} layer on GaAs. Ideally, the distribution of the Mg and Be species should be continuous with the ion implant shape (as in Figure 3a). In the case of Be, however, we observe a significant decrease in the secondary ion intensity within the GaAs matrix. The Mg secondary ion intensity is not strongly affected by the GaAs matrix. Matrix effects are an issue in all SIMS experiments and can be a particular problem in the quantitative analysis of multiphase systems.

Despite these technical issues, SIMS can provide both a qualitative and a quantitative description of the sample in certain instances.\textsuperscript{9} For example, quantitative analysis of homogeneous systems such as glasses and semiconductors is possible, provided that calibration standards are available. In these cases, the secondary ion signal, \(I_i\), is proportional to the primary ion flux, \(I_p\).\textsuperscript{13} The secondary ion signal is related to concentration by Equation (1):

\[
I_i = (AX_iY_j\xi_ie_i\gamma_{i,j}\beta_{i,j}T_{i,j}D_i)I_p
\]

where \(A\) is the fractional abundance of the isotope sampled, \(X_i\) is the average concentration of the element in question within the sputtered atom escape depth (weighted by the relative probabilities of sputtered atom escape from the surface and deeper layers), \(Y_j\) is the sputtering yield of the sample (i.e. the total number of atoms of all species sputtered per incident primary ion), \(\xi_{i,j}\) is the fraction of element \(i\) that is sputtered as the species monitored, \(\gamma_{i,j}\) is a preferential sputtering term, \(\beta_{i,j}\) is the ionization probability of the sputtered element, \(T_{i,j}\) is the mass spectrometer transmission efficiency, and \(D_i\) is the efficiency of the mass spectrometer detector for different elements. Williams\textsuperscript{13} gave a more detailed discussion of the terms in Equation (1).

Despite the fact that researchers have a good understanding of the qualitative aspects of the ionization and the charge-transfer processes in SIMS, a quantitative theory of SIMS still does not exist. Thus, for practical quantitative analysis, one must rely on standards which model the analytical sample. If this requirement is met, all the variables in Equation (1) are calibrated together in a single sensitivity factor, \(K_i\), described by
Equation (2):\(^{(13)}\)

\[ X_i = \frac{K_i I_i}{A} \]  

The proportionality constant depends on the element of interest and the analytical conditions. The data are typically normalized to the secondary ion signal from a matrix element \((I_m)\) to minimize the influence of analytical conditions (Equation 3):

\[ X_i = \frac{K_{i/m} I_i}{A I_m} \]  

The relative sensitivity factor, \(K_{i/m}\), is valid only when \(X\) is a dilute solute in the matrix. Generally, the accuracy of quantitative analyses carried out in this manner is ±10%. Owing to the matrix effects, it is important that the standards are produced from the same matrix as the samples to be analyzed. The most common standards are specific metal alloys developed as National Institute of Standards and Technology (NIST) standards, modified glass materials produced with known levels of impurities, and ion implantation standards.\(^{(14)}\) Ion implantation standards have been particularly useful in the semiconductor industry for depth profiling of silicon wafers. Newbury\(^{(14)}\) gives a more detailed discussion of the role of standards in SIMS.

### 2.2 Static Secondary Ion Mass Spectrometry

In the 1960s, Alfred Benninghoven et al. showed that it was possible to maintain the surface integrity during a SIMS experiment over long periods of time by decreasing the primary ion fluence.\(^{(6,15)}\) In this way, one could preserve the molecular composition of the surface. As described earlier, primary particle bombardment results in (1) the creation of a perturbed region within the surface region (collision cascade) and (2) secondary emission (ions, neutrals, and electrons).\(^{(6)}\) After prolonged primary ion bombardment, the surface will be covered by a large number of “perturbation areas,” \(\sigma\), corresponding to individual ion impacts. The goal in static SIMS is to avoid secondary ion emission from these perturbed or prebombarded areas. This is typically achieved by limiting primary ion bombardment so that \(P \ll 1\) (Equation 4):

\[ P = \frac{\sum \sigma}{A} \]  

where \(P\) is the probability for prebombardment, \(\sigma\) is the damage cross-section and \(A\) is the bombarded target area. The static SIMS limit is then achieved by limiting primary ion beam exposure to no more than \(1 \times 10^{12}\) ions cm\(^{-2}\).
3 INSTRUMENTATION

The main components of a SIMS instrument include the vacuum system, sample introduction, sample manipulation, primary ion source and primary ion optics, secondary ion extraction and transfer optics, energy filter, mass spectrometer, detector, and data acquisition.(16) Modern SIMS instruments are designed to operate under UHV conditions (≤1 × 10⁻⁹ Torr). UHV conditions are required to prevent the loss of secondary ion signal from in-vacuum collisions. Turbomolecular pumps, ion pumps, and titanium sublimators are employed to achieve UHV. Modern SIMS instruments offer rapid sample introduction through a gate-valve-protected sample air lock; in this way, a sample can be quickly exchanged without adversely affecting the main chamber vacuum. Extensive discussions of vacuum components are readily available.(10) Sample manipulation devices are also available to tilt or rotate a sample, and to cool or heat the sample.(16)

Primary ion sources are either reactive or inert gas-phase sources (electron impact or plasma), surface ionization sources, or liquid metal field emission sources. The primary ion optics are used to extract ions from the source, filter out impurities, accelerate and focus the beam toward the sample, and raster the beam over the sample. The secondary ion extraction and transfer optics collect the secondary ions from a defined area inside the sputter region and transfer the ions to the mass filter. Energy filters are used to select ions from the broad energy distribution of the secondary ions sputtered from the surface and to eliminate scattered primary ions.

The mass spectrometer functions to separate the ions of differing mass. SIMS instruments usually employ either a quadrupole mass filter, magnetic sector field, or TOF mass spectrometer. The detector schemes may consist of either a channeltron, Faraday cup, CuBe secondary electron multiplier, or single- or dual-microchannel plate with either a fluorescent screen and camera or resistive anode encoder. Data acquisition in commercial SIMS instruments is controlled by a computer. Imaging SIMS instruments require dedicated data systems with large memories to store intensity distributions of several mass lines. Jede et al.(16) gives a more detailed discussion of instrument components.

3.1 Primary Ion Sources

In general, common primary ion sources include (a) the electron impact ionizer, (b) the plasma ion source, (c) the surface ionization source, and (d) the liquid metal field emission ion source.(16)

3.1.1 Electron Impact Ionizer

A schematic diagram of a gas-phase primary ion gun equipped with an extractor ion source is shown in Figure 4.(16) In this ion gun, an ionizer is placed inside a grounded, differentially pumped housing. A small, grounded aperture between the ionizer/extraction region and the lens arrangement gives a pressure step of three orders of magnitude. The extracted ions are focused by an Einzel lens to form a cross-over in the aperture plane. The tube lens images this cross-over to the sample surface. The typical operating parameters for an extractor type ion source are summarized in Table 3.(16)

3.1.2 Plasma Ion Sources

Plasma ion sources are characterized by the formation of a dense plasma from which ions are electrostatically extracted through a small orifice. The plasma is formed by a low-voltage arc between a cathode and an anode.(16) Because of the high density of charged particles, plasma ion sources are brighter than primary electron impact ionizer sources. With a brighter, higher primary ion flux to the sample, plasma sources have been used extensively in dynamic SIMS applications. The most common plasma

![Figure 4 Schematic diagram of gas-phase primary ion gun equipped with an extractor ion source.](image-url)
ion sources are the hot-filament duoplasmatron source and the cold-cathode duoplasmatron source. In the former case, the cathode consists of a heated tungsten or tantalum filament. The hot filament is used with noble gas (e.g. Ar, Xe, and Ne). In dynamic SIMS applications, the cold-cathode source can be used with O$_2$ to enhance positive ion yield.

A schematic diagram of a cold-cathode duoplasmatron ion source is shown in Figure 5.$^{[16,17]}$ The plasma is constricted by a magnetic field generated by a coil. The primary ions are extracted by a grounding electrode and focused by electrostatic condenser and objective lenses in the optical column. Beam scanning is accomplished by a double-deflection system. The plasma drastically enhances charged particle density and, thus, the primary ion source brightness. This type of ion gun is commonly used on dynamic SIMS instruments. The typical operating parameters for a duoplasmatron ion source are summarized in Table 3.$^{[16]}$

### 3.1.3 Surface Ionization Ion Sources

Surface ionization sources are also important primary ion sources for SIMS because (a) these sources have higher particle density (i.e. high brightness) as compared with duoplasmatron sources and (b) in the case of Cs$^+$ sources, cesium deposition on the surface can enhance negative ion yields.

A schematic diagram of the cesium surface ionization source is shown in Figure 6.$^{[16,18]}$ For this source, cesium vapor from a heated reservoir is led through a heated duct closed by a porous tungsten plug. The Cs$^+$ ions are vaporized by the outside of the plug and are accelerated by an electrical field between the extraction electrode and the suppression electrode. In comparison with duoplasmatron sources, Cs$^+$ sources have a higher primary ion flux and Cs$^+$ deposition on the surface dramatically increases the negative secondary ion yield. Cesium surface ionization sources are well suited for dynamic SIMS applications. The typical operating parameters for a Cs$^+$ source are summarized in Table 3.$^{[16]}$

### 3.1.4 Liquid Metal Field Emission Ion Source

The advent of liquid metal field emission ion sources has brought improvements in microprobe and imaging SIMS.$^{[16]}$ A schematic of a liquid metal field emission ion source, or liquid metal ion gun (LMIG) is shown in Figure 7(a–d).$^{[16]}$

The basic principle of operation is based on the field ion emission process where the surface potential barrier of a metal is modified by very high electric fields. When electrons tunnel into the solid, surface atoms are ionized and desorb in the electric field (field evaporation), as illustrated. The most common liquid metal source is isotopically enriched $^{69}$Ga. The typical operating parameters for an LMIG source are summarized in Table 3.$^{[16]}$

Note that, in time-of-flight secondary ion mass spectrometry (TOFSIMS) instruments the primary ion gun...
must be pulsed to produce a time-resolved “package” of primary ions. Pinkston et al.\textsuperscript{19} gives an additional discussion of the pulsing schemes necessary for pulsed primary ion sources.

### 3.2 Mass Spectrometers

Three different types of mass spectrometers are commonly used in SIMS instruments: quadrupole mass filters, magnetic sector mass spectrometers, and TOF mass spectrometers.

#### 3.2.1 Quadrupole Mass Filters

A schematic diagram of a quadrupole mass filter SIMS instrument is shown in Figure 8.\textsuperscript{16} Quadrupole mass filters work like tuneable, variable-band-pass filters. Only ions within a narrow mass region of $<1$ u are allowed to pass through the mass filter to the detector. Separation over a given mass range is achieved by electronically sweeping the position of the band-pass region.\textsuperscript{20} The quadrupole mass filter consists of a set of four electrodes. The filtering action is obtained by the application of a combination of a time-independent (direct current, dc) potential and a time-dependent (radio frequency, rf) potential. By scanning both the dc voltage and the rf, while keeping their ratio constant, ions of different mass-to-charge ratio ($m/z$) are passed to the detector.\textsuperscript{21} If the dc/rf ratio is constant, then the operation of the mass filter is defined by a straight line which has a zero intercept. This line is known as the mass scan line. Mass separation is achieved by sweeping the voltage applied to the electrode structure such that an ion with a specific $m/z$ is allowed to pass through the center axis to the detector.

#### 3.2.2 Time-of-flight Mass Spectrometers

The basic principle of TOF mass separation is that ions separate according to their velocity in a field-free region. A basic time-of-flight mass spectrometry (TOFMS) system consists of an ion source, ion focusing optics, a field-free drift region and a time-sensitive detector. Since TOFMS instruments measure the flight time of ions, the start of the flight must be known. To produce and coordinate the start time, the primary ion gun is pulsed to produce a time-resolved “package” of primary ions which impinge on the sample. The secondary ions are extracted into the drift tube. Secondary ions are accelerated with a constant kinetic energy, $V_0$ (Equation 5), mass separate according to their velocity (lighter ions striking the detector first, followed by heavier ions) (Equation 6), and are detected after their full TOF (Equation 7):

$$V_0 = \frac{1}{2mz^2}$$  \hspace{1cm} (5)
$$v = \frac{2zeV_0}{m}^{1/2}$$  \hspace{1cm} (6)
$$t = \frac{L}{v}$$  \hspace{1cm} (7)

where $t$ is the ion flight time, $L$ is the field-free flight path length, $V_0$ is the accelerating voltage, $e$ is the unit electronic charge, and $z$ is the number of charges on the ion. The arrival time is then converted to mass via calibration.

In TOFMS, the mass resolving power, $R$, is determined by the width of the ion peaks. Typically, full width at
half-maximum (fwhm) is used to define the peak width (Equation 8):

\[
R = \frac{m}{\Delta m} = \frac{m}{(dm/dt)/\Delta t} = \frac{t}{2\Delta t}
\]

where \( m \) is the mass of the ion, \( \Delta m \) is the fwhm of the ion peak in mass units, \( t \) is the arrival time of the ion, and \( \Delta t \) is the fwhm of the ion peak in time.

Three factors limit mass resolution in TOFSIMS. The first factor is the pulse width of the primary ion source at the sample. The primary ion pulse width introduces variations in secondary ion start time. The second factor is time focusing aberrations of the analyzer. These aberrations contribute to line broadening. The third factor is the rise time and dead time of the detector. A typical mass resolution attainable in TOFSIMS is about 9000 for the \( ^{28}\text{Si}^{+} \) ion desorbed from a clean silicon wafer.

Some of the advantages of TOF mass analysis include very high mass range, high mass resolution, multiplex detection of secondary ions injected into the instrument (i.e. parallel detection) rather than detection of only those for which the analyzer is tuned, and a constant transmission function. In general, TOF SIMS instruments are commonly used for static SIMS applications. Owing to the pulsed nature of the experiment, TOFSIMS instruments are often not well suited for traditional dynamic SIMS depth profiling studies. The duty cycle of the pulsed ion gun is often not sufficient for dynamic SIMS. The dc ion beams used for dynamic SIMS are better suited to the continuous-source mass spectrometers (quadrupoles and magnetic sectors). However, some researchers use TOFSIMS to perform shallow-depth profiling.\(^{(22)}\)

3.2.2.1 Reflectron Time-of-flight Secondary Ion Mass Spectrometry

A schematic diagram of a reflectron TOFSIMS instrument is shown in Figure 9.\(^{(16,23,24)}\) A reflectron is a mechanism to extend the actual flight time of the ions and increase the mass resolution. The secondary ions penetrate into the ion reflector (located at the end of the first drift space). In many reflectron instruments the sample is held at ground potential and the ions are extracted into the drift tube with the opposite sign potential. The ion reflector compensates for flight time dispersion. Faster ions penetrate deeper into and spend more time in the ion reflector field region than slower ions. Thus, a negative flight time dispersion from the initial kinetic energy is compensated for by a positive flight time dispersion in the reflector region. The secondary ions are then registered at the detector. Imaging using a reflectron TOFSIMS system is carried out by raster scanning the primary ion beam across the sample.

3.2.2.2 TRIFT\(^{\circ}\) Time-of-flight Secondary Ion Mass Spectrometry Microscope

A schematic of the TRIFT\(^{\circ}\) TOFSIMS instrument is shown in Figure 10.\(^{(16,25,26)}\) In this design, the sample is held at high voltage potential and the extraction lens is held at ground potential. In the TRIFT\(^{\circ}\) instrument, an image of secondary ions is formed at the immersion lens and the transfer lens; the secondary ion image is extracted into the flight path region, which is defined by three 90° electrostatic sector analyzers (ESAs) with intermediate drift spaces. A spatially resolved intensity–time image is registered at the detector. This is converted to a spatially resolved intensity–mass image via calibration.
Some of the unique features of the TRIFT® instrument are illustrated in Figure 10. A high-mass blanker (1) allows operation at primary ion repetition rates up to 40 kHz without “wrap-around” of high-mass ions into the low-mass region. A SED (2) after the extraction lens allows for static secondary electron detection imaging. An angular filter (3) operates at the cross-over of the secondary ion beam and is used to remove high-energy secondary ions with large angles of emission. An energy slit (energy filter, 4), located between the first ESA and second ESA, is used to filter out low-energy metastable ions. Post-ESA blanking plates (5), positioned at the cross-over in the secondary ion beam, are used to reject individual masses from the beam path before they strike the detector. The TRIFT® TOFSIMS system can be operated in microscope mode or in microprobe mode. In microscope mode, the sample is bombarded with a large-beam-size primary ion beam and the secondary ion image is registered at a position-sensitive detector. In microprobe mode, a small-probe-size primary ion beam is raster scanned across the sample and the secondary ions are registered at a multichannel detector. With the development of 69Ga LMIG sources, superior imaging is now achieved with microprobe mode over microscope mode.

3.2.3 Magnetic Sector Field Secondary Ion Mass Spectrometry

A schematic diagram of a double-focusing magnetic sector field SIMS instrument is shown in Figure 11. Magnetic sector instruments were used in dynamic SIMS depth profiling and imaging. Magnetic sector instruments are more sensitive than quadrupole instruments and can be operated at very high mass resolution.

3.3 Imaging

SIMS imaging is an important component of many modern instruments. Secondary ion images are...
constructed either by raster scanning the primary ion beam across the sample or by using the TRIFT® instrument (discussed above in section 3.2.2) in microscope mode with a position-sensitive detector. With the development of very small-probe-size LMIG sources, raster scanning is the most common technique to acquire images. To collect a raster-scanned image, the position of the primary ion beam is registered along with the mass of each secondary ion detected. From these data secondary ion maps or images can be plotted. These images can be for all of the ions detected (total ion image) or for individual secondary ions. The combination of mass data and lateral position data can be very powerful in analytical problem solving.

3.4 Charge Compensation

SIMS is commonly used to analyze a wide range of materials, including metals, catalysts, semiconductors, and polymers. Special experimental considerations must be given to SIMS of insulating materials. If a primary ion deposits a charge on the surface of a bulk insulator, the material will tend to build up an electrical charge. This static charge will prevent the desorption of any charged particles from the bulk insulator. Since most primary ion sources deliver positive ions, samples charge positively, so charging problems can be particularly troublesome in the negative SIMS mode. Electron bombardment from an electron flood gun is commonly used to dissipate the positive static charge on the surface.\(^{(15,17)}\) In quadrupole-based SIMS instruments, the low-energy electron flood is simply operated simultaneously with the continuous primary ion beam. However, in TOFSIMS instruments, the electron gun must be operated in a pulsed mode and pulses are delivered between primary ion beam pulses. In the case of the TRIFT® TOFSIMS instrument (and also magnetic sector instruments), where the sample floats at high potential, a high-speed switch is used to drop the sample potential to ground during the electron beam pulse, to facilitate charge compensation. Vickerman\(^{(15)}\) gives an extensive discussion of charging and charge compensation schemes.

4 SAMPLE PREPARATION

4.1 Sample Cleanliness

Owing to the surface sensitivity of SIMS and other surface analysis techniques, great care must be taken to preserve the original surface chemistry of the sample. Under static SIMS analysis conditions, only the top few monolayers of the sample are analyzed.\(^{(27)}\) Hence contamination of a surface can be a significant problem. Surface contamination can be of two types: (a) adventitious carbon and (b) contamination due to improper sample handling and/or storage. The former does not present a major problem, but the latter can be very problematic.

Metals and highly reactive materials readily adsorb contaminants from the atmosphere. In fact, the surface of a “clean” metal placed in a UHV system at \(10^{-7}\) Torr will become contaminated in only 1 s.\(^{(28)}\) The degree of contamination depends on a number of factors, including the material’s tendency to adsorb species either from the ambient atmosphere or in vacuum and the cleanliness of the vacuum chamber. Adventitious carbon contamination is commonly observed on metals and is considered to be saturated hydrocarbons.\(^{(29)}\) Although surface techniques “sample” this adventitious carbon layer, the layer is thin enough that it does not completely attenuate the signal from the metal surface below.

Improper sample handling and storage can be problematic. Samples should not be handled by hand because the human fingerprint can readily contaminate the sample. Figure 12 shows a static SIMS spectrum of one of the author’s thumbprints taken from a contaminated silicon wafer.

A substantial amount of contamination can attenuate the detection of secondary ions from the sample. Samples should be prepared with tools (scissors, tweezers, etc.) which are routinely cleaned with organic solvents (e.g. hexane, chloroform, methanol) to remove contamination. Improper sample storage can also lead to contamination. For example, samples stored in certain plastic bags can pick up processing and compounding aids such as N-stearyleucamide or phthalate plasticizers. Figure 13 shows a TOFSIMS spectrum of a plastic bag, where...
the peak at \( m/z \) 338 is the \([M + H]^+\) molecular ion for N-stearylercamide.

Despite the potential sample cleanliness issues, static SIMS can be a very powerful tool for industrial problem solving. Proper sample handling and storage must be considered an integral part of good laboratory practice. An American Society for Testing and Materials (ASTM) guide to handling samples for surface analysis is available.

4.2 Analysis of the Air/Solid Interface

SIMS is applicable to a broad range of materials. SIMS spectra can routinely be obtained from materials such as cured or coalesced polymer coatings, fabrics, silicon wafers, metals, catalysts, and powders. In many of these cases, solid samples are simply mounted on a sample holder and analyzed as received. Supported catalysts and powders can be pressed on to double-sided tape or pressed into cleaned In foil. Again, the tape and In foil should be characterized to ensure that the supporting media do not contribute to sample contamination. SIMS instruments can also be equipped with cryogenic sample introduction and cryogenic stages. In this way, SIMS can be applied to materials with measurable vapor pressures at room temperature.

4.3 Analysis of Solid/Solid Interfaces

Analysis of the solid/solid interface presents some unique challenges since the interface of interest may be well beyond the actual sampling depth of SIMS. Special sample preparation methods such as crater edge profiling, angle lapping, and ball cratering are well known in SAM.\(^{10}\) The general principle here is to lap or cut a sample at a small tilt angle so as to expose the various layers for analysis by an analytical technique with good lateral resolution. Metallic multilayer structures have been prepared in this manner and characterized. Recently, Gardella et al. extended the crater edge profiling methods to polymers, with some success.\(^{31}\)

Several researchers have used traditional cryo-fracturing and cryo-ultramicrotomy specimen preparation methods. Cryo-ultramicrotomy is a tool commonly used in the preparation of ultrathin sections for TEM.

4.4 Bulk Organic Molecule Measurements

While SIMS is a powerful tool for traditional surface analysis, it is also an effective mass spectrometry tool for organic and oligomer molecular weight distribution analysis. A typical sample preparation method for a low-molecular-weight oligomer sample starts with a dilute solution of the analyte in an organic solvent. For example, a low-molecular-weight oligomer sample of polystyrene (PS) 2450 can be prepared for SIMS analysis by preparing a 1 mg mL\(^{-1}\) solution in tetrahydrofuran (THF). The substrate for this experiment is a cleaned piece of silver foil. The silver foil can be cleaned by traditional acid oxidation or by lightly rubbing with a fine-grit emery paper.\(^{6}\) The foil is cleaned by rinsing with solvent. While holding the roughened foil at about a 45° angle to the benchtop, a few microliters of the analyte solution are applied to the top of the substrate. The liquid drop is allowed to flow off the bottom of the substrate. This method delivers a very thin film of analyte to the silver substrate. An example SIMS spectrum of PS 2450 is shown in Figure 14.

An alternative method of sample preparation for liquid organic samples is to apply a small aliquot of the analyte
directly to a piece of filter paper. The analyte will wet the surface of the filter paper and occupy the surface analyzed by SIMS.

A new method of analyzing low-molecular-weight oligomers and biological samples by SIMS is called MESIMS. This method uses sample preparation techniques borrowed from matrix-assisted laser desorption/ionization (MALDI). The following is a typical MESIMS sample preparation for poly(methyl methacrylate) (PMMA) 2900. A 5 mg mL\(^{-1}\) solution of PMMA 2900 is prepared in acetone. An aliquot of this solution is mixed 1:7 by volume with a 0.25 M solution of 2,5-dihydroxybenzoic acid. A few microliters of the resulting solution are applied to a clean aluminum substrate. Figure 15 shows the MESIMS spectrum acquired from this sample preparation.

5 SECONDARY ION FORMATION

5.1 Desorption

As described previously, the SIMS experiment is initiated with the bombardment of the analyte with the primary ion. Figure 16 shows a schematic diagram of the impact of the primary ion on a sample.

The high-energy primary ion impacts the surface of the sample and begins to transfer energy to the sample. The highest energy density from the collision occurs in and around the primary ion impact area. The relatively high energy deposited in this region creates primarily atomic and small-molecule fragment ions. The energy from the primary ion impact is transferred via collisions between atoms and molecules surrounding the impact. This transfer process is called the collision cascade. The energy delivered during any given collision decreases in proportion to the distance from the original impact. Hence ions ejected further from the point of primary ion impact will have experienced less energetic collisions. These ions will tend to be the higher molecular mass fragments and intact molecular ions.

The details of the desorption process are not yet well understood. The basic concepts of the desorption models center around collision cascades that transfer energy first from the primary ion to the molecular structure of the analyte. These collisions continue between different components of the analyte, until a portion of the analyte receives sufficient energy to escape and is desorbed into the gas phase. Many different workers have contributed to these desorption models.

There are two primary desorption models, knock-on sputtering and electronic excitation sputtering. The knock-on sputtering model covers the ejection of target atoms that receive sufficient energy to desorb directly from the primary ion. The electronic excitation model was developed primarily to explain desorption from insulators. It incorporates the idea that excited-state lifetimes may be sufficiently long to allow the transfer of energy from electronic excitation to atomic motion. Both models cover three different regimes (Figure 17a–c) that are concerned with differing numbers of atoms involved in the collision cascade: single knock-on for individual atoms, linear cascade for a small region of moving atoms, and the spike for a large region of moving atoms.

Real systems are probably affected by forces discussed in both models.

Winograd et al. have developed molecular dynamics models to help explain ion desorption. Their models use classical mechanics and examine only pair-wise forces.
Figure 17 Schematic diagrams showing the three regimes of knock-on and electronic excitation sputtering: (a) single knock-on; (b) linear cascade; and (c) spike. (Reproduced by permission from Springer-Verlag.)

between neighboring atoms or atomic ions in the solid. Figure 18(a) and (b) show the results of a desorption model calculation of a thin organic film on a metal substrate from Garrison. (43)

Figure 18 Results from a desorption model calculation of a thin organic film on a metal substrate. (Reproduced by permission of Pennsylvania State University.)

Species that escape the surface are counted as successfully desorbed. These molecular dynamics models tend to treat desorption independently from ionization. While the models must be simplified to allow reasonable computer calculation, they have provided an important insight into the desorption process and good agreement with some experiments. (44,45)

One of the key findings from the molecular dynamics models is that sputtered particles can recombine above the surface. This result has two important consequences: are multimers observed in the SIMS mass spectrum a reflection of the surface being analyzed, and can reactions be an important component of an ionization mechanism? If multimers can recombine with different species after sputtering, the utility of SIMS as a surface structural tool is diminished. For a series of copper clusters and copper oxides, it has been observed that these species were formed by recombination above the surface, but that they were formed primarily from nearest neighbors from the solid. (46) In this example, the structural integrity of the SIMS experiment was maintained. We must keep in mind that ions observed by SIMS may originate from collisions in the selvedge region rather than reflect true surface species. The selvedge region is the space directly above the impact of the primary ion into the sample that is neither solid nor vacuum. It is a relatively high-pressure environment in the transition from solid to vacuum containing both neutral and charged particles.
5.2 Energy Distribution

Once a particle has successfully escaped the surface and has desorbed, it can have a range of kinetic energies. The kinetic energy available to the sputtered particle depends on the energy of the collisions from the collision cascade. It also depends on the size of the particle, including the number of bonds broken to desorb it, any bonds reformed upon sputtering, and any internal degrees of freedom available to disperse energy.

Figure 19 shows a schematic diagram of typical kinetic energy distributions of sputtered atoms and clusters. For typical metal atomic ions, $M^+_1$, we observe a distribution containing ions having from 0 V to more than 20 V of kinetic energy. There is still significant ion intensity in the high-energy tail of the distribution. For typical cluster ions, $M^+_2$ and $M^+_3$, we see fewer ions in the high-energy tail and more ions in the low-energy portion of the distribution. As the chemical complexity of the secondary ion increases, the distribution of kinetic energies tends to decrease.

For sputtered molecular ions we tend to observe kinetic energy distributions that peak at lower energy and have a significantly lower population in the high-energy tail. Since these differences are observed from sputtering by the same primary ion, this result is consistent with the collision cascade delivering a consistent range of energies back to the surface and available for desorption. The more complex molecular species require more energy to desorb, leaving less energy available for kinetic energy. The high-energy tail may disappear for molecular ions because of fragmentation. Those molecular ions with access to energy above 10 eV can readily fragment and are then lost to this kinetic energy distribution.

5.3 Ionization Mechanisms

The particles desorbed due to the impact of the primary ion can be neutral or charged. Charged particles can be readily introduced to a mass spectrometer and mass analyzed. The distribution of charged species to neutral species is completely dependent on the details of each experiment. For most organic samples, most sputtered particles are electrons, followed by neutral species and then secondary ions: secondary electrons $\gg$ neutrals $\gg$ secondary ions. The secondary electrons can be detected with an SED. The sputtered neutrals can be studied by SNMS, a complementary technique to SIMS. The precise mechanisms involved in ionization during SIMS experiments are not fully understood. Good descriptions of different models have been published by Leggett and Vickerman, Cooks et al., and Benninghoven et al. There appear to be at least four different ionization mechanisms in play during a SIMS experiment: bond breaking, preformed intact ions, cationization or anionization reactions, and unimolecular decomposition. Real samples probably have secondary ions produced by each of these mechanisms.

The high energy released in the impact region of the primary ion is sufficient to create a plethora of charged species, from electrons to small molecular ions. These ions are created by momentum transfer from the primary ion. They are primarily atomic ions and are thought to be formed by bond-breaking interactions in the top layer of the sample surface. Once the ion escapes the surface, the relative energy of the ion state compared with the neutral state will determine if the ion is observed.

In samples that have clear preformed ions, such as quaternary ammonium salts, charged species already exist in the solid prior to the primary ion impact. These ion species can be “liberated” by the primary ion impact and readily detected by SIMS. Preformed ions can produce significant SIMS signal intensity because no energy is consumed in a bond-breaking step to form a fragment ion or in an ionization step to form a parent ion. It is clear that preformed ions are important in ionic materials. Benninghoven et al. investigated the role of preformed ions in neutral materials and published studies of the SIMS analyses of peptides on various metal substrates. In these experiments, they observed various $[M + H]^+$, $[M - H]^-$, and $[M + \text{metal}]^+$ secondary ions. The relative intensities of these ions correlated with the chemical activity of the underlying metal substrate. From these data, they concluded that protonated or deprotonated species existed prior to analysis on the metal substrate, “… very high secondary ion yields occur only if the
Neutral species that are desorbed can undergo cationization or anionization reactions in the selvedge region. In the selvedge region there can be many low-energy collisions between desorbed neutrals and atomic ions. These collisions lead to ionization reactions resulting in an adduct between the ion and the neutral. The atomic ions in the selvedge region are created by the bond-breaking interactions described above. The molecular dynamics calculations of Winograd et al. and Garrison discussed in section 5.1 indicate that recombination reactions in the selvedge region is common in SIMS.

Whenever a multi-atomic species is produced in a SIMS experiment, it has the chance of fragmenting after desorption. This is true for both desorbed ions and neutrals. An ion produced by any of the preceding ionization mechanisms can fragment by unimolecular decay if it has sufficient energy. In addition, initially neutral desorbed species can also create ions by dissociative ion formation.\(^{[27]}\) Dissociative ion formation can occur if the ion and neutral potential energy surfaces cross at an appropriate distance from the surface. These fragment ions contain significant chemical information about the surface of the sample. Static SIMS experiments appear to have components of both high-energy mass spectra, such as electron ionization or laser desorption with significant molecular fragmentation, and low-energy mass spectra, such as MALDI, with significant intact molecular ions.

SIMS experiments on real samples probably produce ions by all of these mechanisms. Many of the concepts of these mechanisms have been gathered into a single model. Figure 20 shows a schematic diagram of the desorption ionization model published by Cooks and Busch.\(^{[27,48]}\)

This model separates the processes of desorption and ionization. The energy from the primary ion is transformed into thermal/vibrational motion. Species existing as charged particles in the solid can be desorbed immediately. Desorbed neutral species can be cationized (or anionized) through low-energy collisions in the selvedge region. Regardless of the ionization mechanism, ions can undergo unimolecular decay prior to detection in the mass spectrometer.

6 APPLICATIONS

6.1 Dynamic Secondary Ion Mass-spectrometry Depth Profiling

Ion implantation is a method used for doping the surface of a semiconductor with an electrically active species.\(^{[9]}\) Ion implantation damages the sample and the dopant species may not be located on lattice sites. The sample is then annealed to restore crystallinity and achieve the desired electrical properties. SIMS is well suited to studying the implant distribution in these systems. A typical analysis is shown in Figure 21(a–d).\(^{[9]}\) In this application, dynamic SIMS was used to examine the behavior of Mg implanted into Fe-doped InP as the sample was annealed.

In this example, Fe is present in the semi-insulating substrate and Mg is a p-type dopant. Figure 21(a) shows the typical Mg implant distribution and a uniform Fe doping level. Annealing at 600 °C (Figure 21b) has little effect on the Mg and only a slight redistribution of the Fe is observed. Annealing at 700 °C (Figure 21c) results in Mg diffusion into the InP and also back toward the surface. The profile also shows that Fe appears on the damage sites and is displaced from the bulk material by Mg diffusion. After annealing at 800 °C (Figure 21d), Mg has diffused 3.5 µm into the InP.

TOFSIMS is used extensively to understand polymer additives.\(^{[49–51]}\) TOFSIMS can also be very useful in solving problems. For example, reasons for poor adhesion of poly(vinyl acetate–ethylene) to a poly(vinyl chloride) (PVC) sheet were determined by surface analysis. Positive ion TOFSIMS spectra of two PVC sheets are shown in Figure 22(a) (problem sample) and Figure 22(b) (control sample).\(^{[51]}\) Poor adhesion to the problem PVC sheet was attributed to the presence of polydimethylsiloxane (PDMS), as evidenced by the C₁₃H₂₅Si₂O⁻ ion at 147 u.
Figure 21 Dynamic SIMS depth profiles of Mg implanted into Fe-doped InP. The depth profiles illustrate the effects of annealing: (a) prior to annealing; (b) annealing at 600°C; (c) annealing at 700°C; (d) annealing at 800°C. (Reprinted with the permission of Cambridge University Press.)

and phthalate plasticizer, as evidenced by the C_8H_5O_3^+ ion at 149 u.

PDMS is a common cause of adhesion problems in coating applications. PDMS has a very recognizable pattern of ion peaks.\(^{(49-52)}\) Figure 23 shows a typical static SIMS spectrum containing PDMS.

### 6.3 Static Secondary Ion Mass-spectrometry Analysis of Silicon Wafers Using Time-of-flight Secondary Ion Mass Spectrometry

TOFSIMS is routinely used in the microelectronics industry. Figures 24 and 25 show TOFSIMS spectra from Fe implanted in a silicon wafer. Figure 24 shows the region at nominal mass 29 u. One advantage of TOFSIMS is the ability to obtain high-mass-resolution SIMS spectra. Figure 24 shows four distinct peaks at nominal mass 29 u. We observe $^{29}\text{Si}^+$, $^{28}\text{SiH}^+$, COH+, and $\text{C}_2\text{H}_5^+$. The arrival time difference between the $^{29}\text{Si}^+$ ion and the $^{28}\text{SiH}^+$ ion is only 2 ns. This corresponds to fifteen 138 ps channels on the time-to-digital converter. Figure 25 shows the 56 u mass region, where $^{56}\text{Fe}^+$, $\text{C}_4\text{H}_8^+$, and $\text{Si}_2^+$ are all resolved.

### 6.4 Imaging

One of the more powerful capabilities of many commercial TOFSIMS instruments is to produce chemically sensitive ion images. The development of extremely small spot LMIG sources enables us to obtain secondary ion images with lateral resolution of the order of 1–5 µm length scale. In addition to obtaining high-resolution images, images for individual ions can be collected. The combination of image and mass information can be a powerful tool to solve problems. Figure 26(a–d) shows four
Figure 22 Positive ion TOFSIMS spectrum in the 100–200 u mass range: (a) the problem PVC sample; (b) the control PVC sample, obtained under static SIMS conditions.

Figure 23 Static SIMS spectrum of PDMS low-molecular-weight species.

individual ion images from a microtomed cross-section of an automotive coating sample.\(^{(53)}\)

In Figure 26(a–d), we see chemically sensitive ion images from the various layers of the coating. These images were collected on a TRIFT\(^{6}\) TOFSIMS instrument with a 200 × 200 µm raster using a \(^{69}\)Ga LMIG primary ion source. The Cl\(^{-}\) ion is indicative of the approximately 6 µm thick primer layer, a chlorinated adhesion promoter. The Al\(^{+}\) ion is indicative of the approximately 20 µm thick basecoat. The NCO\(^{-}\) ion is indicative of the polyurethane base coat and approximately 37 µm thick clear coat. Finally, the Mg\(^{+}\) ion is indicative of the substrate. The spots in the Mg\(^{+}\) ion image indicate that the talc in the substrate is present as small (<5 µm) clusters.\(^{(53)}\) These unique secondary ion
images enable static SIMS to identify and probe each layer of this multilayer sample.

6.5 Bulk Polymer Molecular Weight Analysis

SIMS can also be used to provide molecular weight and chemical structure information on low-molecular-weight oligomer samples. As described in section 4.4, we can use traditional monolayer sample preparation or matrix-enhanced sample preparation for low-molecular-weight samples and obtain mass spectra containing intact molecular ions of the oligomers. Figure 27 shows the SIMS spectrum of a sodium-cationized Surlynol® surfactant analyzed using MESIMS.

In the mass spectrum, we see a series of oligomer peaks spaced by 44 u. This Surlynol® surfactant is an ethoxylated alkyne. Figure 28 shows the chemical structure of the Surlynol® surfactants.

The 44 u peaks are the different ethoxylated oligomer chain lengths. From these peak masses we can verify the mass of the alkyne backbone and that the surfactant is ethoxylated. From the distribution of the ion peaks we can calculate the average molecular weights of the material and calculate the average degree of ethoxylation.
MESIMS can also be used in combination with MALDI to investigate the effects of surface segregation in blend analyses.\textsuperscript{(34,55)} For example, we prepared 1:1 molar blends of poly(ethylene glycol) (PEG) 400 and PEG 1000. These very low-molecular-weight oligomers were chosen because we need component samples that can be detected and quantified by static SIMS. Figure 29(a) and (b) show two mass spectra of the 1:1 molar blend of PEG 400 and PEG 1000. The results of the MALDI and MESIMS analyses are given in Table 4.

Whereas we obtain similar measures of the average molecular weights, we observe a significant difference in the measured relative blend composition. Interestingly, under these conditions, neither technique measures a 1:1 molar blend composition. The MALDI analysis shows greater intensity for the higher molecular weight component. On the same sample, MESIMS analysis shows greater intensity for the lower molecular weight component. These experiments provide evidence that components of a sample can segregate during sample preparation. In this case, we observe evidence for segregation of the lower molecular weight oligomers at the surface of the sample.

**Table 4** Comparison of results for a 1:1 molar blend of PEG 400 and PEG 1000

Tandem Mass Spectrometry: Fundamentals and Instrumentation

Edmond de Hoffmann
Catholic University of Louvain, Louvain-la-Neuve, Belgium

1 Introduction

1.1 What is Tandem Mass Spectrometry?

Tandem mass spectrometry (MS/MS) is a methodology which allows selection of ions of a given mass, fragmentation of these ions and detection of the fragments. It requires the use of dedicated instruments of different types. Some of them allow repetition of the ion selection step to fragment fragments further.

This methodology allows structural information on pure compounds or on components of mixtures to be obtained. It also allows highly selective and sensitive detection of target compounds or of compound classes, even from complex mixtures. It is widely used in environmental analysis, pharmaceutical research, biotechnology, forensic science and toxicology, clinical analysis, organic synthesis, process control and many other areas.

1.2 Tandem-in-space Mass Spectrometry

In this approach several separate mass analyzers, most often two, are combined. They are combined in such a way that ions can be transferred from one mass analyzer.
to the other in an instrument schematically represented in Figure 1.

In most cases, a collision cell is placed between the analyzers in order to cause the fragmentation of the ions. These instruments are named *tandem-in-space*, because the combined mass analyzers and collision cells are placed at different locations in space. Common instruments of this type have two mass analyzers, allowing MS/MS experiments to be performed. To obtain higher order MS\(^n\) spectra requires the combination of \(n\) analyzers, increasing the complexity and thus also the cost of the spectrometer.

1.3 Tandem-in-time Mass Spectrometry

The second approach to building a spectrometer with MS/MS capability is to use an ion storage device able to store only ions of selected masses by ejecting the unwanted ones, and as well being able to analyze the ions present in the storage device according to their masses. With such an instrument, the operator can, at least, select ions of a chosen mass, let them fragment either spontaneously or by an artificial excitation and determine the masses and abundances of the ions produced. Alternatively, after the fragmentation step, the operator can select ions of a new chosen mass, let them fragment and analyze the fragments. This process can, at the will of the operator, be repeated several times, in practice up to six generations of ions, thus producing MS\(^n\) spectra. In these instruments, all the procedures take place in one and the same device, so that MS/MS is achieved by successive operations in time. These are time-based instruments. There are two types: ion trap and Fourier transform ion cyclotron resonance (FTICR) instruments. MS\(^n\) experiments are performed in a single device. Figure 2 represents a schematic comparison of a simple MS/MS product ion scan performed by either a space-or a time-based instrument.

**NOMENCLATURE**

The main terms used in MS/MS are listed below.

**Molecular ion**: ion formed by the addition or the removal of one or several electrons to or from the sample molecule.

**Adduct ion**: ion formed through the interaction of two species and containing all the atoms of one of them plus one or several atom(s) of the other.

**Ion of the molecular species or pseudomolecular ion**: ion originating from the analyte molecule by the abstraction of a proton (M−H\(^-\)) or by an hydride abstraction (M−H\(^+\)), or by the formation of an adduct with another ion of the ionizing plasma. These ions allow the molecular weight to be deduced.

**Precursor ion**: (used to be called parent ion) any ion undergoing either a decomposition or a charge change.

**Product ion**: (used to be called daughter ion) ion resulting from the fragmentation of a selected precursor.

**Selected reaction monitoring (SRM)**: monitoring in function of the time of one or several selected product ions from one or more selected precursor ions.

**Neutral loss**: fragment lost as a neutral species

**Source spectrum**: spectrum acquired with a single analyzer.

2 ION DISSOCIATION

2.1 Stable and Metastable Ions

Some ions have received a sufficient amount of energy to dissociate before leaving the source and are designated *source ions*. Ions that are stable in the source but have excess internal energy can dissociate spontaneously during flight in the analyzers to the detector; these are *metastable ions*. The other ‘stable’ ions normally reach the detector without fragmentation. However, to increase the number of fragment ions, dissociation can be induced by activation, or energy transfer to the ion. The most common way to achieve this is by collision with an inert gas.

2.2 Collision Energy

The kinetic to internal energy transfers are governed by the laws concerning collisions of a mobile species, the ion, and an essentially static target, the collision gas.
Figure 3 Vectorial demonstration of the link between the position vectors in the laboratory and in the center of gravity reference frames.

Consider an ion with mass \(m_1\) hitting a target with mass \(m_2\). If \(\mathbf{R}\) represents the position vectors in the laboratory reference frame \(O\), and \(r\) represents the position vectors in the reference frame linked to the center of gravity \(G\), Figure 3 shows that Equations (1) and (2) follow:

\[
R_1 = R_G + r_1
\]

and

\[
R_2 = R_G + r_2
\]

Defining the center of gravity by Equation (3):

\[
(m_1 + m_2)R_G = m_1R_1 + m_2R_2
\]

thus Equations (4) and (5) follow

\[
r_1 = \frac{m_2(R_1 - R_2)}{m_1 + m_2}
\]

and

\[
r_2 = -\frac{m_1(R_1 - R_2)}{m_1 + m_2}
\]

Differentiating with respect to \(t\) gives Equations (6) and (7):

\[
u_1 = \frac{m_2\mathbf{\dot{g}}}{m_1 + m_2}
\]

and

\[
u_2 = -\frac{m_1\mathbf{\dot{g}}}{m_1 + m_2}
\]

where \(\mathbf{\dot{g}} = v_1 - v_2\) and \(m_1u_1 + m_2u_2 = 0\) and where \(u\) is the velocity in the \(G\) (center of gravity) frame and \(v\) the velocity in the \(O\) (laboratory) frame.

According to the law of momentum conservation, the kinetic energy of a rapid particle colliding with a static target \((v_2 = 0)\) cannot be entirely converted into internal energy. The kinetic energy available for conversion, \(E_t\), termed relative kinetic energy, is actually the kinetic energy in the center of mass reference frame. Indeed, in this \(G\) frame the momentum is equal to zero. We thus obtain Equation (8)

\[
E_t = \frac{m_1u_1^2 + m_2u_2^2}{2} = \frac{\mu\dot{g}^2}{2}
\]

where \(\mu = m_1m_2/(m_1 + m_2)\). Thus Equation (9) follows

\[
E_t = E_c \frac{m_2}{m_1 + m_2}
\]

where \(E_c = m_1v_1^2/2\).

The kinetic energy is conserved in an elastic collision, Equation (10)

\[
\frac{\mu\dot{g}^2}{2} = \frac{\mu\dot{g}^2}{2}
\]

In an inelastic collision, a part \(Q\) of the kinetic energy, at a maximum equal to \(E_t\), is converted into internal energy, Equation (11):

\[
\frac{\mu\dot{g}^2}{2} = Q + \frac{\mu\dot{g}^2}{2}
\]

For instance, a 100 Da ion with a kinetic energy of 10 eV colliding with argon (atomic mass 40 Da) has a maximum increase in its internal energy amounting to \(10 [40/(40 + 100)] = 2.86\) eV.

Always keep in mind that 1 eV per ion is equivalent to around 100 kJ mol\(^{-1}\).

This calculation supposes a totally elastic collision between spherical species.

A measure of the average amount of kinetic energy converted into internal energy in the collision process was obtained by Harrison and Lin.\(^{(1)}\) They observed that the fragmentation of the \(n\)-butylbenzene molecular ion gives two fragments, \(C_7H_7^+\) and \(C_7H_8^{++}\) and that the ratio of their intensities increases with increasing amount of internal energy of the parent ion \(C_\mu H_\nu H_\chi^{++}\) measured by charge exchange. Nascent and Harrison\(^{(2)}\) using similar techniques, concluded that 87% of the available collision energy is converted into internal energy for collision of 60 eV \(n\)-octylbenzene with an \(N_2\) target while the efficiency decreases to 33% for \(n\)-butylbenzene with an \(Ar\) target.

In practice, two collision regimes should be distinguished: low energy, in the range of 1–100 eV, as occurs in quadrupole or ion trap instruments, and high energy, several thousands of electron volts, as is common for magnetic instruments.

For theoretically comparable energy exchange, as calculated by Equation (9), different fragmentation patterns are observed for low and high collision energy. Generally, high-energy spectra give simpler, more clear-cut fragmentations, while low-energy spectra lead to spectra with more diverse fragmentation pathways, often including more rearrangements.
3 TANDEM MASS SPECTROMETRY SCAN MODES

3.1 Product Ion Scan

Time-based MS/MS instruments can produce fragment ions from one or several selected precursors, but can only do this over several ion generations, yielding MS^n spectra. On the other hand, instruments with several mass analyzers in space can be scanned in several ways. The most important ones for two analyzers are displayed in Figure 4.

In the first scan mode an ion of a chosen \( m/z \) is selected with the first spectrometer. This ion collides inside the collision cell and fragments. The reaction products are analyzed by the second mass spectrometer. This is a fragment ion scan or product ion scan. This method used to be called a daughter scan. Symbolism describing the various scan modes is represented in Figure 5. This fragment ion scan mode is represented by the product ions scan symbolism.

3.2 Precursor Ion Scan

In the second scan mode, the second spectrometer (MS2) is focused on a selected ion, while the masses are scanned using the first spectrometer (MS1). All of the precursor ions that produce ions with the selected mass through reaction or fragmentation are thus detected. This method is called precursor scan because the precursor ions are identified. It used to be called parent scan. Using the symbolism of Figure 5, it is represented by the precursor ions scan symbolism.

3.3 Neutral Loss Scan

In the third common scan mode, both mass spectrometers are scanned together, but with a constant mass offset between the two. Thus, for a mass difference \( a \), when an ion of mass \( m \) goes through the first mass spectrometer, detection occurs if this ion has produced a fragment ion of mass \( (m - a) \) when it leaves the collision cell. This is a neutral loss scan, the neutral having the mass \( a \). For example, in chemical ionization positive ions containing an hydroxy group very often lose a water molecule. Alcohols are thus detected by scanning a neutral loss of 18 mass units. On the other hand, a given mass increase can be detected if a reactive gas is introduced within the collision cell, but this is not frequently applied. The symbol for this scan mode is that of the neutral loss scan in Figure 5.

3.4 Selected Reaction Monitoring

For SRM, both the first and second analyzers are focused on selected masses. There is thus no scan. The method is analogous to selected ion monitoring in standard mass spectrometry (MS). But here the ions selected by the first mass analyzer are only detected if they produce a given fragment, by a selected reaction. The absence of scanning allows one to focus on the precursor and fragment ions over longer times, increasing the sensitivity as for selected ion monitoring, but this sensitivity is now associated with a high increase in selectivity. This is often used to detect a selected compound in an elution timeframe during chromatography. The high selectivity corresponds to a low probability of detecting an

![Figure 4](image1)

![Figure 5](image2)
interfering compound. This reduces the background noise and eliminates most interferences. If required, it allows the time taken for the chromatography to be shortened. This scan mode is represented by the symbol for SRM in Figure 5.

4 IN-SPACE INSTRUMENTS

Many of these instruments are built especially to perform MS/MS. However, some instruments allow MS/MS experiments to be carried out with just small modifications in the instrument, most often electronic parts.

4.1 Electric/Magnetic Sector Instruments

Basic instruments in this category combine an electric sector (E) with a magnetic sector (B), in the order BE or EB. The ion paths in these sectors have respectively radii \( R_E \) and \( R_B \).

If the geometry of the instrument is BE, a product ion scan can be performed in the following way. The field of the magnetic sector is set to allow ions of a given mass to pass. If the electric field is held at its normal value, that is the value used for standard scans, the ions of this selected mass will arrive at the detector. Fragmentation may occur between the magnetic and electric sectors, either because metastable ions spontaneously fragment, or because a collision cell has been inserted between the two sectors in the second field free region, as displayed in Figure 6.

An important basic feature of fragmentations is that the velocity \( v_f \) of the fragments is almost the same as that of the precursor ions \( v_p \), thus \( v_f = v_p \). However, the mass has changed, \( m_p \neq m_f \) and thus so also have the momentum and the kinetic energy. The value of the electric field \( E \) that will allow an ion to pass depends on its kinetic energy by the relation, Equation (12):

\[
qE = \frac{mV^2}{R_E}
\]

where \( R_E \) is the radius of the ion path in the electric sector and \( q \) the electric charge of the ion \( (q = ze, z \) is the number of elementary charges). If we consider now the values of \( E \) required to focus successively the precursor and the considered fragment, Equations (13) and (14) are obtained:

\[
qE_p = \frac{m_pV^2}{R_E}
\]

\[
qE_f = \frac{m_fV^2}{R_E}
\]

The ratio of these two electric field values is equal to the ratio of the masses, Equation (15):

\[
\frac{E_f}{E_p} = m_f \frac{m_p}{m_f}
\]

\( E_f \) is measured, while \( m_p \) and \( E_p \) are known. Thus, \( m_f \) can be determined. Scanning \( E \) allows all the fragments of the selected precursor to be detected successively. Actually, what is measured is not the mass, but the kinetic energy of the fragment. This is why the method is called MIKE spectroscopy. If some kinetic energy is released during the fragmentation, for instance by the opening of a strained small cyclic structure or relaxation of steric interaction, this will result in a small dispersion of the kinetic energy, leading to a broadening of the peak while scanning \( E \). This broadening allows the kinetic energy released to be measured quantitatively.

Another way to obtain fragment ion spectra from sector instruments of either BE or EB configuration is to use a B/E linked scan. Remember that after fragmentation the product ions have the velocity of the precursor, but differ by the mass. As the focusing condition in a magnetic sector is given by Equation (16)

\[
qB = \frac{mV}{R_B}
\]

where \( B \) is the magnetic field, \( R_B \) is the radius of the guide tube in the magnetic sector, \( q \) is the charge of the ion, \( m \) is its mass and \( V \) is its velocity. Applied to a precursor ion and one of its fragments, Equations (17) and (18) are obtained:

\[
qB_p = \frac{m_pV}{R_B}
\]

\[
qB_f = \frac{m_fV}{R_B}
\]

Figure 6 Schematic diagram of an electric/magnetic sector mass spectrometer. One of the two S1 or S2 sectors is an electric sector E, while the other is a magnetic one, B. The two field free regions FFR1 and FFR2 can be used to fragment precursor ions. If FFR2 is used, mass analyzed ion kinetic energy (MIKE) spectroscopy is performed and a BE configuration is needed. If FFR1 is used, the configuration may be either BE or EB. S is the source and D the detector.
The ratio of these two equations gives Equation (19):

\[
\frac{B_t}{B_p} = \frac{m_t}{m_p}
\]  

(19)

The corresponding focusing conditions for the electric sector have been deduced for MIKE spectroscopy and are expressed by Equation (20):

\[
\frac{E_t}{E_p} = \frac{m_t}{m_p}
\]  

(20)

As they both equal the ratio of the fragment mass to the precursor mass, one can write Equations (21) and (22):

\[
\frac{E_t}{E_p} = \frac{B_t}{B_p}
\]  

(21)

or

\[
\frac{B_p}{E_p} = \frac{B_t}{E_t}
\]  

(22)

Thus, to select a precursor ion, the operator adjusts the values of \(B\) and \(E\) to those used for that ion in normal scan. The precursor ion is therefore focused in both sectors. Then, both sectors are scanned together in such a way that the ratio \(B/E\) remains constant and equal to \(B_p/E_p\). The successive fragment ions are detected and the mass assigned from either the corresponding \(B\) or \(E\) value. The name \(B/E\) linked scan has been coined for this scan mode. Other scan modes such as precursor or neutral loss scans can also be performed by other linked scans of magnetic instruments, but are rarely used.

4.2 Multiple Sector Magnetic Instruments

Many combinations of more than two sector magnetic instruments are in use. Figure 7 displays an instrument with BEEB configuration. Many more types of experiment can be performed with such elaborate instruments. First, high resolution can be achieved in principle both for precursor selection and for product ion analysis. It should be noted however that sensitivity is lost when the resolution is increased. Because the collision process also results in the loss of the majority of the ions, more than one high resolution stage is almost never used, and one only rarely. Some very specific analyses, such as quantification of dioxine, require a high-resolution selection of the precursor ions.

To analyze ions with a sector analyzer, the ions must have about the same kinetic energy. If, for example, ions fragment in the field-free region after the first two BE sectors, in FFR3, the fragments will not have the same kinetic energy because, as described before, they will all have the velocity of their precursor but different masses. This means that the last two sectors must be scanned in the \(B/E\) linked scan mode. For different precursors, different calibrations of the two last sectors are needed.

An alternative way is to slow down the ions, make the collisions at low energy, i.e. a few electron volts, and then reaccelerate at several kiloelectron volts. This allows there to be product ions with about the same kinetic energy, but many ions are lost in the process. There is also still some dispersion in kinetic energy, which reduces the resolution that can be obtained.
A single quadrupole mass spectrometer cannot be used to perform true MS/MS experiments. However, with an electrospray source it is possible to cause the ions to fragment by adjusting the kinetic energy of the ions in a region where the gas density is still high enough to cause collisions. If under normal conditions, the source produces only ions of the molecular species, these collisions will produce fragments and thus produce a kind of MS/MS fragment ion spectra. However, if fragment ions are present or if a mixture is analyzed, all the fragments or all the ions of the different species will fragment together. This is, of course, avoided by using a true MS/MS instrument, which permits the selection of ions of a chosen mass. Instruments that include two quadrupole mass analyzers (Q) separated by an RF-only (radio frequency) quadrupole collision cell (q) are the most common tandem-in-space mass spectrometers available (Figure 8). They are symbolized QqQ, where Q stands for a quadrupole mass analyzer, while q refers to a quadrupole collision cell.

Quadrupoles have the advantage of being true mass filters. Magnetic sectors separate ions according to their momentum, electric sectors according to their kinetic energy, time-of-flight (TOF) instruments according to their \( m/z \) velocities, but quadrupoles according to their values. They are largely not sensitive to variations in kinetic energy and thus do not require special scans of the second analyzer or special calibration. The drawbacks are the impossibility of obtaining high resolution, a lower sensitivity in the higher mass region and the limitation of using only collisions at low energy. Besides their lower cost, their success is due to the great ease of their use.

To be used as a mass analyzer, both an RF and a DC (direct current) potential have to be applied together on the rods. If only a RF potential is applied, ions of all \( m/z \) values above a given low mass cutoff are allowed to pass. This low mass limit depends on the applied RF potential and is usually set at \( m/z \ 4 \). The advantage of using a RF-only quadrupole as a collision cell is the focusing property of this cell. When ions collide with a target and fragment, the fragment ions produced are scattered in all directions and a majority of ions are lost. The use of an RF-only quadrupole causes the ions to be refocused at the center of the quadrupole. This can be visualized by comparison with a ball on a saddle, as represented in Figure 9. A positive ion will travel toward the negative rod, but owing to the frequency of oscillation of the field, the polarity of the positive rods will quickly change to negative and vice versa. This change in polarity can be compared to a saddle on which a ball has been placed. The ball will roll down the slope, but if the saddle is quickly rotated by 90°, the rolling ball will face uphill and will roll back to the center of the saddle. If there are several balls and the trajectories change by collision between them, they will be driven back to the center by the effect of the fast...
rotating saddle. This is what happens to the ions in the central quadrupole. Even if they undergo collisions with a neutral gas in the cell, the effect of the RF will be to bring them back to the center. This prevents the loss of ions by scattering after collision.

An offset voltage between the source and this RF-only quadrupole can be adjusted to allow the collision energy to be varied between zero and several hundred electron volts. This is low compared with magnetic instruments where the usual values are fixed somewhere in the range 2–10 keV. However, under normal operating conditions, a relatively large number of collisions can occur in the collision cell, causing the build-up of energy in the precursor ions. Conversion of precursor ions to fragments can usually occur to a much larger extent than possible with a magnetic sector instrument. Important advantages of triple quadrupole instruments are the relatively lower cost and ease of use. Once both quadrupole mass analyzers have been calibrated, switching between different scan modes and mass ranges can be done instantaneously. Furthermore, unit resolution on both quadrupole mass analyzers is obtained for all types of MS/MS experiment.

Instruments with more than two quadrupole mass analyzers have been constructed in research laboratories, but have never been used commercially. A review paper has been published on QqQqQ instruments.\(^{(5)}\)

### 4.4 Time-of-flight Mass Spectrometers

When ions fragment, the fragments have almost the same velocity as their precursors and will thus not be distinguished by their TOF. However, if the instrument is equipped with a reflectron device, then MS/MS can be performed. This is best achieved by combining a linear with a reflectron spectrometer, as shown in Figure 10. When an ion fragments, its product ions have the same velocity as the precursor and thus the same flight time in the absence of any field. However, they will have different kinetic energies. If \(m_p\) is the mass of the precursor and \(m_f\) the fragment mass, their respective kinetic energies \(K_p\) and \(K_f\) are (as they have the same velocity \(v_{ix}\)) given by Equations (23) and (24):

\[
K_p = \frac{m_p v_{ix}^2}{2} \quad (23)
\]

and

\[
K_f = \frac{m_f v_{ix}^2}{2} \quad (24)
\]

thus \(K_p/K_f = m_p/m_f\) or \(K_f = K_p m_p/m_f\).

The penetration depth \(x\) in the reflectron is given by \(x = K/qE\). Hence, for the precursor and the fragment,

\[
x_p = \frac{K_p}{qE} \quad (25)
\]

and

\[
x_f = \frac{K_f}{qE} = \frac{K_p (m_f/m_p)}{qE} \quad (26)
\]

Hence Equation (27)

\[
x_f = x_p m_f/m_p \quad (27)
\]

The respective flight times in the reflectron are given by Equations (28) and (29)

\[
t_{rp} = \frac{4x_p}{v_{ix}} \quad (28)
\]

and

\[
t_{rf} = \frac{4x_f}{v_{ix}} = \frac{4x_p (m_f/m_p)}{v_{ix}} \quad (29)
\]

Hence Equation (30)

\[
t_{rp} = 4x_{rp} m_f/m_p \quad (30)
\]

This demonstrates that the time spent in the reflectron will be shorter for the fragment than for the precursor, the ratio of the respective times being equal to the mass ratio. Thus, as shown in Figure 10, the TOF will be the same for the precursors and fragments in the linear mode, but will differ in the reflectron mode. When comparing the two spectra, ions observed in the reflectron spectrum but

---

**Figure 10** MS/MS with combined linear and reflectron TOF instrument. • = Bunch of ions with one given mass leaving the source; during the flight, a fraction of these ions fragments; ● = Survivor ions; ○ = Fragment ions. Those ions fragmenting between the source and the reflectron are called post-source decay (PSD) ions. (Reproduced from de Hoffmann et al.\(^{(6)}\))
not in the linear mode result from PSD fragmentations having occurred between the source and the reflectron device.

An alternative method involves detecting the neutrals with a linear detector. This method requires the acceleration of the ions at several tens of kiloelectron volts, typically 30 keV, in order to have enough kinetic energy in the neutrals to be detectable. This is illustrated in Figure 11.

If the instrument is fitted with electrodes after the source on the ion path, a precursor ion can be selected to analyze its fragmentation by PSD. As shown in Figure 12, a potential is applied to eliminate the ions. Cutting off this potential for a short time, corresponding to the passage of the ions with a given mass allows these ions to be selected. The resolution on modern (1998) instruments is about 50. This gives a \( m/z \) 20 window at \( m/z \) 1000. The mass of the passing ions can be determined in the linear flight mode, while the fragments are observed in the reflectron mode.

Cornish and Cotter have developed a compact laser desorption tandem TOF mass spectrometer. The instrument incorporates two dual-stage reflectron analyzers separated by a collision region for producing ions by collision-induced dissociation (CID) (Figure 13). The first reflectron provides energy focusing while the second provides both energy focusing and time dispersion of ions having different masses.

They introduced a curved field reflectron to allow the recording of product ion spectra without stepping or scanning of the reflectron potential.

5 IN-TIME INSTRUMENTS

5.1 Ion Trap-based MS

Instruments with ion storage capabilities, i.e. ion traps or ICR (ion cyclotron resonance) cells, allow “in-time” multiple stage MS experiments to be performed with an appropriate time sequence of events, as represented for simple MS/MS experiments in Figure 2. Ion traps, like quadrupole instruments, rely on oscillating electric fields to operate, while ICR instruments make use of a magnetic field to store the ions associated with oscillating electric fields to perform the various mass spectroscopic experiments.

A schematic representation of an ion trap is given in Figure 14.

Ion traps can be operated in various ways, by applying DC and RF voltages to the ring electrode or to the end caps. However, in commercial instruments, a ring RF voltage is applied to the ring electrode. Additional RF voltages are applied between the end caps for MS operations. These are the ion injection, ion expulsion, ion selection and ion excitation RF voltages.

To understand the MS/MS operation in an ion trap, let us first recall the typical stability diagram for an ion trap as represented in Figure 15. From Equation (31)

\[
\rho^2 = 2z_0
\]  

then Equations (32) and (33) of the coordinates of this stability diagram, \( a_z \) and \( q_z \) can be written for
Figure 14 Schematic representation of an ion trap. It is composed of one ring electrode and two end cap electrodes. $z_0$ is the distance from the center to the end cap and $r_0$ is the radius of the ring electrode.

Figure 15 Typical stability diagram for a quadrupole ion trap. (Redrawn from March and Hughes (1992) (Figure 3.62).)

monocharged ions respectively:

$$a_z = -\frac{8eU}{mr_0^2\Omega^2} \quad (32)$$

$$q_z = -\frac{4eV}{mr_0^2\Omega^2} \quad (33)$$

In these equations, $e$ is the charge of a monocharged ion ($1.6 \times 10^{-19}$ C), $U$ is the DC voltage applied to the ring electrode, $r_0$ is the radius of the trap in centimeters with a typical value of 1 cm, and $\Omega$ (impulse or angular velocity) is equal to $2\pi v$, where $v$ is the frequency of the RF potential, and $V$ is the amplitude zero to peak in volts of this RF voltage. The common order of magnitude of the frequency is around 1 MHz and $V$ varies between about 0 and 7000 V. An ion will only have a stable trajectory if its $a_z$ and $q_z$ values are inside the boundaries indicated in the diagram. These boundaries depend on a $\beta$ stability parameter, whose values have to be between 0 and 1 in both the $r$ and $z$ directions.

Iso-$\beta_z$ lines are also displayed in Figure 15. $\beta_z$ can be calculated from $a_z$ and $q_z$. For $q_z$ lower than 0.4, it can be approximately calculated from Equation (34):

$$\beta_z = a_z + \frac{q_z^{1/2}}{2} \quad (34)$$

We will now consider, as is the case for most commercial ion traps, that $U = 0$, and thus $a_z = 0$. Thus, the ion trap operation line is on the $q_z$ axis. In the expression of $q_z$, $-4e$ is a constant term for monocharged ions, and $r_0$ and $\Omega$ are constant for a given ion trap. Then $q_z$ is proportional to $V/m$; for ions with a fixed mass $m$, $q_z$ will be proportional to $V$. Respectively, at a fixed $V$ value, ions with higher masses will be characterized by a lower $q_z$ value.

It is important for MS/MS that ions will oscillate at a secular frequency $f_z$, linked to the ring electrode RF

Figure 16 At a fixed value of the RF potential $V$ applied to the ring electrode, heavier ions will have lower $\beta_z$ values and thus lower secular frequencies. If $V$ is increased, $\beta_z$ values increase for all the ions, and thus also the secular frequencies. In the example given, the lightest ion now has a $\beta_z$ value larger than one and is thus expelled from the trap.
frequency $v$ by Equation (35):

$$f_z = \frac{\beta_z v}{2}$$  (35)

As the maximum value for $\beta$ is 1, it follows that the maximum secular frequency $f_z$ for an ion with a stable trajectory will be $v/2$.

Thus at a given $V$ value, ions of mass $m$ will oscillate at a frequency $f_z$. If an RF voltage of this same frequency $f_z$ is applied between the end caps, it will be in resonance. Thus these ions will oscillate with a larger and larger amplitude, depending on the amplitude of the applied RF voltage and the time. If this amplitude is low, ions will progressively gain energy and dissociate by collisions with helium gas, which is always present in the trap. At higher amplitude, the ions will be quickly expelled from the trap in the $z$ direction.

Figure 16 shows ions whose masses are represented by the volumes of the spheres. It shows that for a fixed value of the amplitude $V$ of the RF potential applied to the ring electrode, ions with a lower mass have a larger $\beta_z$ value, and thus a higher secular frequency $f_z$. If $V$ is increased, the secular frequencies of all the ions increase.

By irradiation at all the frequencies except the one corresponding to ions of a selected mass, all the ions can be expelled from the trap except the selected ones. This is achieved by irradiation with an appropriate waveform, calculated by inverse Fourier transformation (Figure 17). This is the SWIFT method, selected waveform inverse Fourier transform. Alternatively, the waveform can be applied during ion injection from the source. Only ions of one selected mass are then stored; this is also used in selected ion monitoring.

---

**Figure 17** (a) Ions from the source are stored in the trap. These ions are irradiated by applying a waveform to the endcaps. (b) Only the ions whose secular frequency was absent in the waveform remain in the trap. (c) The ring RF potential $V'$ is changed to adjust the secular frequency of the selected ions to the excitation frequency applied to the endcaps. (d) Fragment ions are produced. The smallest will be expelled because it is not within the stability boundaries. Afterwards, the fragment ions can be analyzed, or the sequence of isolation/excitation can be repeated on one of the fragments; if this is repeated $(n-1)$ times, an $\text{MS}^n$ experiment is performed.
After ions of a selected mass have been stored, fragmentation must be induced. To do this, it is possible to rely on multiple collisions of the ion with the helium damping gas. Fragmentation can be improved by causing the ions to oscillate at an increased amplitude, which can be performed as explained before by irradiating the ions at their secular frequency. Often, a fixed frequency is used for irradiation. Then the secular frequency of the selected ions must be adjusted by changing the V amplitude of the circular electrode RF potential. This process is illustrated in Figure 17. To be observed, fragment ions have to be inside the stability boundaries, i.e. $0 < \beta_z < 1$. Generally, fragments whose mass is less than about 25% of the mass of the precursor will be lost. This sequence of ion isolation, excitation, and analysis of the product ions can be repeated on one of the fragments. This can be done $n$ times, allowing observation of successive generations of ions in a MS$^n$ experiment. Typically for analytical purposes a maximum of five or six steps are used.

An advantage of ion traps in comparison with beam instruments is the high efficiency of ion transmission. When an ion is fragmented, the total ion current of the fragments can be 100% of the ion current of the fragmented precursor ion. In practical use, this transmission is at least 50%. For beam instruments, this figure is somewhere between 1 and 10% typically. The advantage of this efficiency increases exponentially with the number of fragmentation stages.

### 5.2 MS$^n$ in Ion Cyclotron Resonance Fourier Transform Mass Spectrometry Instruments

In an ICR cell, ions exposed to an axial $B$ magnetic field and having a charge $ze$ have a cyclotron motion with frequency given by Equation (36):

$$\omega_c = \frac{zeB}{m}$$

(36)

Thus, monocharged ions will have, for a given value of $B$ depending on the instrument, a frequency inversely related to their mass. They can be detected by the current they induce in the wall of the cell, in a nondestructive way. This is a distinct feature of ICR, important in MS/MS experiments. By applying an AC (alternating current) electric field perpendicular to the axis, it is possible to excite ions, or to expel ions by discharge on the wall. This allows one to expel all the ions except those having a selected mass. These ions are then allowed to fragment over time. Sometimes a collision gas is introduced for a short time to induce fragmentation by collision, and excitation by irradiation at the cyclotron frequency is also used. However, sustained excitation at the resonance frequency results in larger cyclotron radii and fragment ions are then produced with nonzero magnetron radii. It is now common practice to use sustained off-resonance irradiation (SORI). This results in ions being alternatively accelerated and decelerated, limiting the cyclotron radius. The fragments are then produced close to the center. Fragments are detected while they are formed in a nondestructive way. They can be detected repetitively, increasing sensitivity and resolution. The selection and fragmentation process can then be repeated, providing MS$^n$ capability without reloading ions from the source, as the detection is not destructive. This contrasts with the situation in ion traps, where the detection of ions empties the trap which has then to be reloaded from the source.

However, the magnetic field has no focusing properties. Over time, there is an off-axis displacement of the center of the ion cyclotron orbit, known as magnetron radial expansion. Reaxialization can be performed using the focusing properties of a quadrupolar AC electric field (see Figure 9). Combined with collision damping, this allows the magnetron radial expansion to revert and greatly improves the resolution and the sensitivity, especially by reducing the loss of ions during MS/MS experiments. High resolution can be obtained on both precursor and fragment ions.

### 6 HYBRID INSTRUMENTS

Hybrid instruments are made by combining different types of mass analyzer to obtain a tandem mass spectrometer. Many hybrid instruments have been built. The most common ones result from coupling a magnetic instrument with a quadrupole, either in the BEqQ or the EBqQ configuration. Between the last sector and the RF-only quadrupole, ions must be decelerated from kiloelectron volts typical of magnetic instruments to tens of electron volts needed for quadrupole analysis.

If this is performed before CID fragmentation, all the ions leaving the magnetic instrument have the same kinetic energy, and deceleration occurs at the same potentials for all. CID then occurs in the RF-only quadrupole, at low energy, and fragments are analyzed by the last quadrupole.

Alternatively, CID can be effected in a collision cell at the focal point at the exit of the last sector. High-energy collisions occur. The ions are then slowed down before they enter the quadrupole stage. However, all the ions no longer have the same kinetic energy, because after collision, fragment ions have the same velocity
and thus lower kinetic energy than their precursors. The ions must therefore be slowed down by a difference of potential on the electrodes varied as a function of the mass.

Another instrument combines a magnetic or quadrupole mass spectrometer with an orthogonal TOF analyzer. As already mentioned, when ions fragment during their flight, with or without CID, precursor and fragments have the same velocity and will arrive together at the detector. If however they are accelerated perpendicularly to their flight in the TOF mass spectrometer, they will arrive at different times at the array detector and will thus be detected according to their mass. Figure 18 displays the scheme of such an instrument.

The combination of a quadrupole analyzer, a quadrupole collision cell and a reflectron TOF analyzer gained in importance in 1998. The reflectron TOF allows high-resolution spectra to be obtained, with typically a 10,000 resolution.

These instruments are used especially in the area of protein analysis. Short sequences of amino acids from an unknown protein can be compared using a database to find out to which protein they correspond. The efficiency of this search is greater if the mass is known with accuracy.

Another advantage of this high resolution is that it allows the charge state of ions to be determined. Indeed, electrospray ionization (ESI) produces multiply charged ions. From a statistical analysis, the charge state $z$ can be determined and thus from the measurement of $m/z$, the mass $m$ of the protein can be assigned.

If a multiply charged ion is selected as a precursor in MS/MS, the assignment of the charge state of the fragments is not straightforward. However, if the precursor ion is selected with a sufficiently low resolution, the natural isotopes will be included. As they have an entire multiple Dalton difference, they will appear in the mass spectrum at $m/z$ values at a distance of $1/z$ from each other. This is illustrated in Figure 19.\(^{15}\)

---

**Figure 18** Principle of the combination of a mass spectrometer with an orthogonal TOF spectrometer. Ions arriving from the mass spectrometer are directed to the detector. When a pulse voltage is applied on the orthogonal acceleration repeller, the ions are analyzed by the TOF instrument. Faster ions will arrive farther along the array detector. (Reproduced from de Hoffmann.\(^{14}\))

**Figure 19** Product ion spectrum of the $[M + 7H]^{7+}$ ion from the peptide ALVRQGLAKVAYVYKPNNTHEQHLRK-SEAQQKEKLLNISEDNADSGQ. Fragment ions having lower charge number $z$ may appear at higher $m/z$ values than the precursor, which indeed occurs in the spectrum shown. The inset shows that, owing to the high resolution, the isotopic peaks appear at a distance of $1/z$ mass units, and thus $1/z = 1/6$ or $z = 6$. (Reproduced with permission from Andersen et al.\(^{15}\))
As the resolution is defined as \( \frac{m}{\delta m} \), the required resolution is 887/(1/6), i.e. about 5400. TOF instruments with a reflector have resolutions in the 10000–20000 range.

7 ANALYTICAL METHODS BASED ON TANDEM MASS SPECTROMETRY

7.1 Structure Elucidation

An example of structure elucidation by MS/MS is displayed in Figure 20. The FAB ionization mass spectrum of an isolated fraction contains several nodulation factors appearing at different \( m/z \) values. One of them, \( m/z \) 1244, is selected and fragmented using a \( B/E \) linked scan on a magnetic instrument. The observed fragment ions suggest the structure shown, corresponding to features known for this class of compounds, i.e. an oligosaccharide bearing at one end an alkyl chain bound to an amino sugar.

The analogy to a chromatographic separation coupled to a mass spectrometer should be mentioned. In this case, the FAB mass spectrum is analogous to a chromatographic trace displaying compounds of the mixture. The \( B/E \) linked scan yields the mass spectrum of one of these compounds. While chromatography gives a separation requiring a long time, the separation according to the mass is almost instantaneous, providing a much shorter analysis time.

Another typical example of structure determination by MS/MS is the widely used sequence determination of peptides. As an example, an ESI spectrum of mellitin obtained by a hybrid magnetic orthogonal TOF instrument is displayed in Figure 21. The notation of the fragments is as shown in Scheme 1.

This example also illustrates the clear-cut fragments obtained from a doubly charged ion produced by ESI: doubly charged fragments, appearing at lower \( m/z \) values, belong to the \( b \) series, while monocharged ones, some of which...
them appearing at \( m/z \) higher than the precursor ion, belong to the \( y \) series.

\]

MS/MS also allows the determination of isomers. As an example, the product spectra of the acylglycerol pseudomolecular ions contain a type of ion whose formal mass-based composition corresponds to a ketone obtained by the combination of two fatty acid chains with a carbonyl group, minus a proton. The ketone contains mainly the chains of the central fatty acid combined with one of the two external fatty acids, even if a ketone containing the two external fatty acids is always present with a much weaker intensity. The formation of these ions may be explained by an internal Claisen condensation followed by a fragmentation and a decarboxylation, as is shown in Figure 22. The expulsion of the ketone containing the hydrocarbon chains of the central fatty acid combined with one of the outermost fatty acids (Figure 22, pathway c) requires the formation of a neutral epoxide, which is faster than the neutral oxetane formation necessary for the expulsion of the ketone resulting from the condensation between the two outermost fatty acids (Figure 22, pathway f).

This method can be directly applied to acylglycerols present in a mixture, as is illustrated by the mass spectrometric analysis of natural cocoa butter.\(^{(17)}\) This analysis, Figure 23, allowed the determination of the complete structure of the predominant acylglycerols in this cocoa (Table 1).

### 7.2 Determination of Diastereoisomers

Glycosylmonophosphopolysoprenols\(^{(18,19)}\) display abundant \((M-\text{H})^-\) ions in the negative ion FAB mode.

When these ions are fragmented under low-energy collisions, an abundant fragment corresponding to the phospholipid anion is observed, together with fragments across the sugar ring. This fragmentation is very sensitive to the stereochemistry, as illustrated in Figure 24. Decaprenylphospho-D-ribose displays the decaprenylphosphate anion as almost the sole fragment,

while the analogous D-arabinose derivatives also produce fragments resulting from cleavage across the sugar ring.

From a study of several compounds, it appears that a 2-hydroxy group trans to the phosphate strongly favors the formation of the phospholipid anion. The ribose derivative differs from the arabinose derivative only by the trans configuration of the 2-hydroxy group with respect to the phosphate.

7.3 Methodology for Compound Class-selective Detection

A typical methodology to develop class-selective analysis of mixtures will now be illustrated. Figure 25 displays the CID product ions spectrum of octanoylcarnitine and a corresponding fragmentation scheme is shown in Figure 26. A typical feature of this product ion spectrum is the absence of isotopic masses. Indeed, the selected...
TANDEM MASS SPECTROMETRY: FUNDAMENTALS AND INSTRUMENTATION

Figure 24 FAB CID at low collision energy of the (M–H)− anion from the decaprenylphosphates of β-D-ribose (a) and β-D-arabinose (b), respectively. The trans configuration of the 2-OH and phosphate groups in β-D-ribose favors the formation of the phospholipid fragment. (Reproduced modified from Wolucka and de Hoffmann,19 with permission.)

Precursor ion (m/z 288) contains only the main isotopes 12C, 1H, 14N and 16O. At this low precursor kinetic energy (2 eV), few fragments are observed. From the interpretation of this spectrum, useful scan modes that detect carnitine conjugates selectively from different fatty acids can be found. This is important because the presence of carnitine conjugates in body fluids is diagnostic of several metabolic diseases and carnitine itself is used as a drug in some of these diseases.

Referring to the scheme in Figure 26, it can be seen that precursor scans of m/z either 144 or 85 are good candidates. Indeed, these fragments do not contain parts of the fatty acids and should thus not be sensitive to their nature. The fragment ions at m/z 229 (M-59) and 127 (M-161), acylium ion obtained after loss of the carnitine moiety, contain the fatty acid chain and thus are not good candidates for precursor ion scans that would detect all the carnitine conjugates. However, the neutrals lost in these fragmentations contain a part (59 Da) or the complete (161 Da) carnitine moiety. A neutral loss scan of either 59 Da or 161 Da should thus also allow the selective detection of all the carnitine conjugates.

Figure 25 Product ions spectrum of octanoylcarnitine. For the nature of the fragments, see the fragmentation scheme in Figure 26.

Figure 26 Fragmentation scheme of acylcarnitines, as deduced from the fragment spectra of octanoylcarnitine and confirmed by the spectra of other carnitine conjugates.
Figure 27 (a) FAB mass spectrum of a biological sample of acylcarnitines. (b) Same sample, but precursor scan of $m/z$ 85, $m/z$ 162: free carnitine, 204: acylcarnitine, 218 propionylcarnitine, etc. A comparison of these two spectra shows that the selectivity of the MS/MS scan strongly improves the signal-to-noise ratio (S/N). (Reproduced from de Hoffmann et al.\textsuperscript{6})

in a complex mixture. This is largely used in the pharmaceutical industry to monitor and quantitate a selected compound in pharmacokinetic studies.

Figure 28 (a) FAB spectrum of a mixture of bile acids extracted from a physiological sample. (b) Selective detection of the sulfated bile acids by the neutral loss scan of 80 Da (SO$_3$). This spectrum displays compounds completely buried in the chemical background of the FAB spectrum. (Reproduced from Libert et al.\textsuperscript{7})

7.4 Increase in Sensitivity by Tandem Mass Spectrometry

MS/MS also allows the S/N to be substantially improved in the detection of selected compounds or compound classes. This is illustrated by the spectra in Figure 28. The first spectrum is a FAB/MS spectrum (source spectrum) of a mixture of a physiological sample of bile acids.\textsuperscript{20} Some of these bile acids are sulfated and for the diagnosis of biliary atresia it is important to detect them selectively. In the negative ion mode, sulfated bile acid loses SO$_3$, 80 Da, on CID fragmentation of the [M–H]$^-$ precursor anion. A scan of this neutral loss is displayed in the second spectrum. It shows that sulfated bile acids buried in the chemical background of the source spectrum are now clearly detected, such as those appearing at $m/z$ 560, 578, 594 and 610. This is because selective detection does not apply to most of the components in the background, thus
strongly reducing the background. As sensitivity depends on S/N, this example also shows that MS/MS can greatly improve the sensitivity towards selected compounds, especially when analyzing complex mixtures. It should be noted that this increase in sensitivity is observed even if actually more than 90% of the ions are lost in the fragmentation process.

The possibility of obtaining both high selectivity and high sensitivity by MS/MS means that it is often used in pharmacokinetics, which is the field that uses the largest number of tandem mass spectrometers. The example shown in Figure 29 illustrates that a good S/N can be obtained from a plasma sample spiked with 0.05 ng mL\(^{-1}\) (i.e. 50 ppb) of the drug, with a total chromatography time of only 2 min and elution after 0.5 min.

8 FIELDS OF APPLICATION OF TANDEM MASS SPECTROMETRY

Modern mass spectrometers can ionize and assign the m/z for a large variety of compounds, including...
nonvolatile ones, such as proteins, synthetic polymers, oligosaccharides, and so on up to more than 100 000 Da. Easy gas chromatographic coupling is now extended to HPLC (high-performance liquid chromatography) and other separation techniques such as capillary electrophoresis.

MS/MS increases the capacity of the technique by allowing more efficient structure elucidation, selective detection, increase in sensitivity and faster mixture analysis. This makes MS/MS useful and it is now largely applied in almost all areas of organic and biochemical compounds analysis. Some areas, however, use more MS/MS than others. Pharmaceutical applications are the main domain of application of MS/MS, judged by the number of instruments used.

The development of combinatorial chemistry methods has created the need for faster structure determination or verification and selective compound class determination. The parallel development of faster and more reliable in vitro tests to check metabolization has led to the tendency to check the rate of metabolization of new compounds earlier in the development process of a new drug. Here again, MS/MS is very useful. There are a few main metabolization routes leading to important expected phase II metabolites: glucuronides, sulfates, or glutathione conjugates. These can be easily detected by compound class-selective MS/MS methods. If a compound is quickly metabolized and eliminated, it is most probably not worthwhile to try to develop it as a drug. The US Food and Drug Administration has issued a recommendation to the pharmaceutical industry to perform such in vitro tests.

Furthermore, before approval of a drug, pharmacokinetics on the metabolites from human volunteers belonging to a representative panel of various ethnic origins have to be performed. Here again, MS/MS, coupled to HPLC, is the method of choice, as it allows fast sensitive analysis of target compounds.

Toxicology and clinical analysis also need highly selective and sensitive detection of target compounds, and MS/MS is developing quickly in these areas.

Proteomics has emerged as an important new application area in 1997 and 1998. More is known about the genomes by the sequencing of nucleic acids, and for some species it has been completely determined. Once the DNA sequence is known, the sequences of the corresponding proteins can be deduced. There is a great interest now in determining where those proteins, if expressed, are located and what is their role in the living cell. Because many proteins often act together in multistep synthesis, it is important to be able to determine which proteins are located in a delimited part of the cell. MS allows the molecular masses of proteins to be obtained quickly and MS/MS yields information about the sequence. As molecular masses combined with short sequences allow the identification of proteins in a database, established from the DNA sequence, MS/MS is again the method of choice for assigning the part of the genome from which a group of proteins originate.

Environmental pollution control uses MS widely, still mainly gas chromatography coupled to MS. HPLC/MS is becoming more frequently applied for nonvolatile compounds. MS/MS can be applied with cost affordable instrumentation and because it allows faster, more selective and sensitive detection, it is expanding fast in this field too.

9 CONCLUSIONS

MS/MS has many outstanding advantages as an analytical technique: high sensitivity into the femtomol range, rich structural information, high selectivity for the analysis of target compounds. As MS/MS can be applied to volatile or nonvolatile compounds, even with high molecular weights and can be coupled to separation techniques such as gas or liquid chromatography, its areas of application are very broad.

These advantages are increasing continuously with the development of instruments with still better performances and cheaper instrumentation. The future of MS/MS thus appears to be very bright.

This article reviews the developmental history, fundamental technology, and general applications of time-of-flight mass spectrometry (TOFMS). The fundamentals of instrument operation and components are discussed. Applications in terms of gas chromatography (GC), liquid chromatography (LC), capillary electrophoresis (CE), laser desorption, multiphoton desorption, plasma desorption (PD), matrix-assisted laser desorption, surface-enhanced laser desorption, inductively coupled plasma (ICP), and secondary ion mass spectrometry (SIMS) are presented. A review of tandem time-of-flight (TOF) techniques with a focus on ion trap TOF instrumentation is provided.

The purpose of this article is to provide the reader with a fundamental understanding of TOFMS principles and applications. Information is presented in a simple, straightforward, didactic fashion.

1 INTRODUCTION

During the past decade, the technology of TOFMS has demonstrated impressive development and analytical popularity. As is the case with all mass spectrometers, a TOFMS system consists of two major components: an ionization source (roughly the sample introduction means: also known as the interface or inlet system) and the mass analyzer (the mass measurement and ion detection portion). Present-day TOF mass analyzers are routinely interfaced with solid-state, gaseous, and liquid samples. Currently, there are some 15 different manufacturers of commercial TOFMS analyzers for use in surface investigation, life science studies, elemental analysis, as well as inorganic and organic chemical analysis (see Table 1).

Conceived in 1946, the fundamental strengths of this mass analyzer when compared to other contemporary devices drove an initial phase of growth and acceptance during the late 1950s and early 1960s that resulted in a 1964 worldwide base of more than 200 units. Indeed, these strengths were readily recognized by many of the TOF pioneers. To begin with, the TOF analyzer is remarkably simple in its concept, operation, and design. Compared with quadrupole radiofrequency (RF)-mass filter, magnetic sector, and ion trap mass analyzers, the moderate mechanical alignment and machining requirements for the TOF analyzer mitigated the need for extreme alignment and fabrication tolerances, greatly simplifying the manufacturing and installation processes while concomitantly improving product reliability. Such inherent simplicity has resulted in the creation of several simple-to-use, inexpensive, small devices. Undoubtedly, this trend toward miniaturization and improved simplicity will continue in the years to come.

In terms of analytical performance, the TOF analyzer excels in a number of capabilities. Because scanning mass analysis is performed without the use of time-dependent changing magnetic or electric fields, the TOF analyzer demonstrates an extraordinarily fast scan speed and associated high scan-mode duty cycle. Mass analysis is generally accomplished by employing uniform, static electric fields and, as such, system response time is solely dependent upon ion introduction time, ion extraction rate, and the velocity of the heaviest ion of interest. Ions may be formed within the extraction region or in an outside area requiring about 1–2 ms to enter the extraction region. Modern TOF devices intended for use in continuous-flow gas- or liquid-phase analysis are capable of extracting ions at a rate of $10^4$–$10^5$ cycles per second. Furthermore, the flight time for an ion of about 50 000 m/z is roughly 260 µs (15 keV energy, 2.0 m free flight). Accordingly, the duty cycle becomes ultimately limited by the TOF of the heaviest ions. The latter results in nominal duty cycles of 5–50%. This high scan rate and associated duty cycle makes the TOF device the molecular weight (MW) detector of choice for many fast chromatographic techniques such as capillary GC, CE, micro and capillary LC, as well as capillary electrochromatography (CEC).

Another analytical strength of TOFMS is its mass range. Because mass assignment is solely dependent upon ion flight time, the mass range of the TOF instrument is theoretically unlimited. However, practical limitations of ionization and detection efficiency do play governing roles. Even so, singly charged organic polymers approaching 1.0 mDa in mass have been detected using MALDI. Furthermore, the same technique has successfully detected singly charged ions of human immunoglobulin M (IgM) at ~980 kDa, whereas TOFMS with ESI has been employed to detect multiply charged ions of single-stranded and double-stranded DNA in the 1.0–5.0 mDa range.

The high ion transmission properties of the TOFMS instrument, particularly linear TOF devices, make it perhaps the most sensitive scanning mass spectrometer. In a linear TOFMS instrument, overall ion transmission efficiency is primarily regulated by ion transverse velocity spread. Other losses occur when ions collide with grid elements of ion optical components. Such effects are typically controlled by employing gridless, radial ion focusing means, high ion accelerating voltages, and reasonably sized ion detectors. In this manner most of the ions formed are efficiently collected, accelerated, and transmitted down to a detection apparatus. Because no slits or energy-selective filters are employed, minimal ion loss due to unimolecular decay occurs, and products of unimolecular decay can be detected with high efficiency at the same time as their parent ions. This makes this device ideal for the analysis of ion species with very short lifetimes. As will be demonstrated later, subfemtomole levels of detection for even large, labile molecules such as bovine immunoglobulin G (IgG, ~148 kDa) is possible with reasonable signal-to-noise levels.

Without doubt, the coupling of the TOFMS analyzer with the soft ionization techniques of MALDI and ESI has enabled facile mass spectral analysis of complex biological samples and has been a primary driving force behind the recent growth and popularity of this approach. A good portion of this article will be dedicated to describing these techniques. However, equally important to this rapid adoption curve are recent technological advances in laser design; high-voltage electronics; high-speed digital and broad-bandwidth analog electronics; as well as high-speed, high-voltage pulsing technology. Because of the latter, MALDI and ESI TOFMS analyzers are now capable of providing low parts-per-million mass accuracy and a mass resolving power ($m/\Delta m$) in excess of 20000, greatly enabling empirical studies and the ability to identify and characterize unknown biopolymers.

This article provides a brief historical review of TOFMS and then proceeds to describe the fundamental theory and components of TOF mass spectrometers. A number of different TOF geometries and ion interfaces are...
discussed, along with exemplary applications. The goal is to provide new and future users of this technique with sufficient knowledge to allow for intelligent decisions regarding the appropriate use, limitations, and possible selection of TOF instrumentation.

Because the scope and required expertise to attain successfully the goals of this article are quite demanding, this work is the product of the combined efforts of a number of expert contributors. The section addressing gas chromatography/time-of-flight mass spectrometry (GC/TOFMS) is authored by Stephen Davis; the section covering inductively coupled plasma/time-of-flight mass spectrometry (ICP/TOFMS) is authored by Alexander Makarov; the section addressing liquid chromatography/time-of-flight mass spectrometry (LC/TOFMS) is authored by Randy Whittal; the section reviewing TOFSIMS is authored by Steven Thompson; the section describing QIT/TOFMS (quadrupole ion trap) is written by Randy Purvis; and all other sections were provided by Scot R. Weinberger.

2 A HISTORICAL PERSPECTIVE OF TIME-OF-FLIGHT MASS SPECTROMETRY

Stephens first suggested the concept of TOFMS in 1946. In a brief correspondence, he envisaged a simplified mass spectrometer utilizing no magnets or slits, with a high duty cycle and a millisecond scan period, amenable for gas composition control, rapid gas analysis, as well as portable use. Although noting that such a device was being constructed, actual published data from this work was not seen until 1953.

In 1948, Goudsmit described a virtual instrument that introduced and accelerated ions in a homogeneous magnetic field. Under such conditions, he noted that these ions would assume helical trajectories with angular velocities independent of initial ion velocity and release direction. The latter minimizes the perturbing effects of varied initial ion position and energy upon mass resolving power and mass assignment accuracy. In this case, ion TOF was described to be directly proportional to ion mass and inversely proportional to magnetic field strength. This analyzer was ultimately constructed and described in 1951. Although initially shown to be successful, this approach had a limited practical mass range, because heavier ions require increasingly larger helical path radii, mandating a large system footprint and excessive vacuum requirements. Consequently, this geometry has been effectively abandoned.

In 1948, Cameron and Eggers provided the first published data from a TOF mass spectrometer. This device was a gas-phase TOF analyzer known as an “Ion Velocitron”. The instrument was a constant-energy, linear TOF mass spectrometer in which gas-phase ions were created using an EI source and accelerated to constant energy by a three-element ion gun. After acceleration, ions traveled down a 317-cm long drift tube to strike ultimately a charge collector plate that functioned as an ion detector.

A constant-energy TOF device functions by accelerating all ions to the same level of kinetic energy. In this manner, ions will assume velocities as defined by Equation (1), where \( v \) is final ion velocity, \( e \) is ion charge, \( V \) is acceleration voltage, and \( m \) is ion mass:

\[
v = \left( \frac{2eV}{m} \right)^{1/2}
\]  

(1)

Ion TOF is the product of free flight distance and \( 1/v \). Resolution for this approach is defined by Equation (2) where \( R \) is resolution (a unitless entity), \( T \) is the ion flight time and \( \Delta t \) is the peak width at half-height of the measured ion signal:

\[
R = \frac{T}{2\Delta t}
\]  

(2)

Demonstrated resolution for the analysis of analytes ranging from 1 (H\(^+\)) to 200 (Hg\(^+\)) Da by the ion velocitron was of the order of 2–3. The authors accurately attributed the limited resolving power to nonmonoenergetic ion populations and ion multipath trajectories. Although providing limited mass resolving power, mass accuracy, and MW dynamic range, the device did incorporate a number of advanced technological approaches, such as differential vacuum pumping, a resistor high-voltage dividing network to establish ion optic potentials, a pulsed electrostatic ion deflector used for ion bunching, and a post-source focusing lens assembly used for beam collimating and steering.

In 1953, Wolff and Stephens published results from the instrument first described in 1946. This device was the first to employ pulsed ion extraction (PIE). Furthermore, a 0.5-\( \mu \)-s-wide pulsed EI source was used to generate ions within a multiple-lens ion optic assembly. For constant-energy TOF operation, the ion extraction pulse was applied for a period of time sufficiently long to allow complete extraction of all ions of interest. In another mode of operation – constant momentum or impulse TOF analysis – the ion extraction pulse was applied and then shut off prior to the time required for any ions to leave the extraction region. In this fashion, ions were accelerated to final velocities that were inversely proportional to their mass. Hence, all ions had constant momentum.

Final ion velocity in impulse TOFMS is described by Equation (3), in which \( E \) is the applied ion acceleration
field and $T_p$ is the duration of the ion extraction pulse:

$$v = \frac{E T_p e}{m}$$  \hspace{1cm} (3)

It can be shown that resolution in an impulse TOF analyzer is defined by Equation (4):

$$R = \frac{T}{\Delta t}$$  \hspace{1cm} (4)

A quick comparison of Equations (2) and (4) would lead one to believe that improved mass resolving power would be obtained by employing the impulse TOF approach in lieu of the constant energy approach, should a constant degree of ion time spread be realized in each system. Indeed, Wolff and Stephens noted the apparent resolution advantage of impulse TOF and they spoke of improved resolution for heavier masses using this technique. However, they did realize that thermal velocity distributions creating nonmonoe energetic ion populations would also limit resolving power. Katzenstein and Friedland further substantiated this in 1955.\(^{(21)}\) Mathematically, they demonstrated that thermal spread greatly minimized the resolving power of constant-impulse TOF measurements and that, under these conditions, constant-energy TOF was favored. They constructed a pulsed-ion-extraction, constant-energy TOF device that demonstrated a fivefold improvement in resolving power when compared to the constant-impulse device of Wolff and Stephens.

Later in 1955, Wiley and McLaren introduced a new dual-stage ion gun providing improved ion focusing.\(^{(3)}\) In the same publication, they also introduced the landmark PIE technique of time-lag focusing (TLF), capable of correcting for initial ion spatial or initial ion energy spread, and providing previously unattainable mass resolving power. This technique is described at length in section 6.1. In their device, the primary limit to resolution was determined to be the spatial distribution of ions formed by their EI source. Employing TLF, unit mass resolution for ions as large as 300 Da was achieved for the first time. All modern TOFMS systems utilize some form of TLF during the ion extraction duty cycle.

Bendix Corporation (Detroit, MI) ultimately commercialized the TLF technology of Wiley and McLaren, as described by Wiley in 1956.\(^{(22)}\) The Bendix TOF device had extended the resolvable mass range out to about 600 Da and demonstrated about 1 ppm sensitivity for gaseous analytes in “the low mass range”. The system incorporated a magnetic electron multiplier detector that provided of the order of $10^8$ gain.\(^{(23)}\) This technology was ultimately sold to CVC Products (Rochester, NY).\(^{(24)}\)

Overall, the Bendix TOF system proved to be highly successful and was modified by a number of researchers, adapting it to a plurality of ion sources and a wide range of applications (see Table 2).

During the 1960s, TOF devices were also interfaced to a number of light-based ionization sources. In 1964, Isenor interfaced a TOF device with a Q-switched ruby laser ($\lambda = 694$ nm) to evaluate the effect of laser fluence upon the initial kinetic energy of ions desorbed from Zn, Pb, and Mg targets.\(^{(29)}\) Lincoln (1965) used a high-intensity, xenon flash tube to desorb and ionize cellulose, inorganic compounds, and ions from meteor fragments prior to analysis in a Bendix Model 14-107 TOFMS system.\(^{(30)}\) In 1966, Fenner and Daly used a short-pulse-duration Q-switched ruby laser to generate ions from thin metal foils prior to analysis in a 1.0-m TOFMS system.\(^{(31)}\) Vastola and Pirone (1968) interfaced a frequency-doubled ruby laser ($\lambda = 347$ nm) to a Bendix 12-107 TOFMS system to analyze various polyaromatic hydrocarbons prepared in a pyrite matrix.\(^{(32)}\)

In the mid-1970s, a significant advancement in the technology of laser-based ionization TOF instruments occurred in the creation of the laser microprobe mass

analyze (LAMMA). Hillenkamp (1975) converted a laser microprobe microscope device into a laser desorption/ionization TOFMS ion source. The system utilized a frequency-doubled, Q-switched ruby laser to desorb successfully and ionize a number of epoxy-doped metals. In 1978, Hillenkamp linked a frequency-doubled ruby laser, a frequency-quadrupled neodymium laser (\(\lambda = 265\) nm), and various nitrogen lasers (\(\lambda = 337\) nm) to a linear TOF system and analyzed alkali metal and divalent cation profiles within thin tissue slices of frog skeletal muscle. Hillenkamp’s efforts later became commercialized by Leybold–Heræus (Koln, Germany) as the LAMMA 500, a simple linear TOF analyzer, and as the LAMMA 1000, which utilized a reflectron TOF mass spectrometer.

Significant growth in the use of TOFMS analyzers occurred shortly after the introduction of a number of soft ionization techniques that enabled the analysis of poorly volatile analytes, particularly biopolymers. Prior to the introduction of such techniques, molecules such as enzymes, amino acids, proteins, nucleic acids, oligonucleotides, oligosaccharides, and glycoconjugates remained refractory to mass spectral analysis when employing electron impact, thermal and flash pyrolysis, as well as early photoinduced ionization means. Biopolymers exhibit extensive intermolecular attractive forces in aqueous and solid states and, as such, possess extremely low vapor pressures. Under such circumstances, it is difficult to create gas-phase neutrals for subsequent ionization and mass spectrometry (MS) analysis. In this case, the simplest method for increasing biomolecule vapor pressure is to heat the sample. However, biopolymers are known to be exquisitely heat labile and, as such, decompose when subjected to elevated temperatures over an extended period of time.

Initial attempts to perform biomolecular MS analysis involved the use of chemical derivatization. In this manner, polar groups of biological compounds are modified to nonpolar substituents. These nonpolar groups do not produce the strong intermolecular interactions of their predecessors, and the modified compound exhibits significantly elevated vapor pressure. Such approaches have successfully linked gas chromatographic separation of some temperature-stable biocompounds, such as small lipids and carbohydrates, to MS analysis.

To provide effective MS analysis of thermally labile biocompounds, volatilization should be achieved with a minimal amount of decomposition. In this fashion, parent ions of the nascent biomolecule may be studied in a mass spectrum that is relatively free of artifact fragment ions. The latter allows for the analysis of complex biomolecular mixtures, where multiple compounds are simultaneously present, as well as the study of possible biopolymer modifications, where subtle mass differences between populations exist due to post-translational modifications or other biomediated changes.

Parent ion fragmentation typically occurs through unimolecular decay mechanisms when the heat of volatilization excites the molecule to unstable vibrational states that result in bond schism. The rate of decomposition is primarily determined by the time needed to deposit energy into the unstable vibrational mode and by the vibrational period. Consequently, if the rate of surface vaporization exceeds that of unimolecular decay, most desorbed ions should have sufficient time to cool, thus minimizing the yield of fragment products. However, volatilization is only part of the process. Ultimately, a volatized neutral molecule must be ionized for MS analysis.

The means by which volatilized neutral molecules are ionized also plays a role in unimolecular decay dynamics. With respect to biomolecules, ionization is typically achieved through the addition or deletion of a proton (H\(^+\)) and less frequently via the addition or deletion of an electron (e\(^-\)), or the addition of some metal ion. Varying degrees of ion fragmentation will result if the addition of the charging species creates excessive internal excitation. Such phenomena have been discussed in the case of chemical ionization (CI) and MALDI. In the final analysis, successful MS investigation of labile biopolymers must utilize a volatilization and ionization technique that does not facilitate excessive unimolecular decay. Such techniques have been loosely termed as being soft.

The first greatly successful soft ionization technique applied to the analysis of biopolymers was californium-252 PD, originated by Macfarlane et al. In this approach, samples are prepared as solid-state crystals or films upon thin nickel foils. Desorption and ionization are achieved using the high-energy fission products of 252\(^{\text{CF}}\) decay. Spontaneous fission of 252\(^{\text{CF}}\) is asymmetric, producing two nuclei of uneven mass and energy, released in opposing directions. Typical products such as 142\(^{\text{Ba}}\)\(^{18+}\) and 186\(^{\text{Te}}\)\(^{22+}\) emerge with respective kinetic energies of 79 and 104 meV. One of the pair of liberated fission products is directed to pass through the foil, whereas the other is directed toward a fragment detector, which is used to create the time zero mark for the TOF measurement. It was initially believed that the high-energy fragments that passed through the sample foil created a thermal spike that vaporized quantities of mobile impurity ions upon the foil surface (mostly H\(^+\), Na\(^+\), and H\(^-\)). These secondary ions would then react with the sample molecules in the region of the thermal spike to produce parent molecular ions. Later it was believed that the thermal spike created a desorbed molecular dimer, which in turn would split up into two parent molecular ions of opposite charge.
Macfarlane et al.\textsuperscript{(39)} mated this desorption/ionization source with a linear TOF mass spectrometer. Two different devices were noted. One device had an 8-m-long flight tube and was used for high-resolution experiments. The second device utilized a 1.5-m-long flight tube and was used for high-sensitivity measurements. PD TOF technology was ultimately commercialized by Bio-Ion AB (Uppsala, Sweden).

PD has been applied most successfully to the analysis of peptides and proteins.\textsuperscript{(37,40)} Although identified as a soft ionization technique, evidence of unimolecular decay and prompt parent ion fragmentation was noted from the onset.\textsuperscript{(39)} The potential for such prompt fragmentation was demonstrated to increase with increasing MW. The level of desorption energy deposited by \textsuperscript{252}Cf fission products was eventually recognized as being too high for the analysis of large, labile proteins. The effective mass limit of this technique was found to be about 50 kDa.\textsuperscript{(41)} Although widely employed from the late 1970s through to the 1980s, this technique was ultimately abandoned after the advent of MALDI and ESI.

In 1981, Chait and Standing interfaced a pulsed alkali metal ion gun to a simple linear TOF mass spectrometer known as Manitoba I.\textsuperscript{(42)} The pulsed ion gun provided a desorption and ionization means for samples that were deposited as a thin layer of solid-state crystals or films upon a solid support target. When these pulses of primary ions struck the target, they liberated secondary ions. This ionization technique is known as SIMS and section 15 of this article is dedicated towards further discussion of this technique. The combination of SIMS with a TOF analyzer has been colloquially coined as TOFSIMS.

Chait and Standing reported the successful analysis of bio-ions with \textit{m/z} up to 1355 Da. Later, they adapted a similar pulsed SIMS source to a reflectron TOF mass analyzer (Manitoba II).\textsuperscript{(10)} This device demonstrated a mass resolving power \textit{m}/\textit{dm} of up to 10000 and was used to detect successfully the parent molecular ions of bovine insulin: MW = 5733 Da. Using this device, they reported the detection of unimolecular decay products from ions generated during this process. Consequently, this ionization technique was not totally “soft”.

TOFSIMS devices are used extensively today, but primarily for surface analysis. The use of TOFSIMS for biopolymer analysis has been greatly diminished since the advent of MALDI and ESI approaches.

In the late 1970s, another soft ionization technique known as multiphoton ionization (MPI) emerged. In this approach, samples are introduced as a gaseous molecular beam\textsuperscript{(43)} or solid.\textsuperscript{(44,45)} Direct ionization of the gaseous beam is accomplished while solid samples are typically desorbed using an infrared laser. An ultraviolet or visible laser is used to provide ionizing photons. Gas-phase neutrals absorb several photons, exciting them to an energy level equivalent to the total energy of the absorbed photons. In this manner, even visible light can lead to ultimate ionization. Initial photon absorption causes electronic transitions from the ground state ($S_0$) to an $S_1$ excitation state, and subsequent photon absorption results in further transition to an ionization phase where electron loss results in the creation of a gaseous cation. Should the wavelength of the ionizing laser match the absorbance maxima of the neutral’s $S_1$ state, so-called resonance MPI occurs, allowing selective ionization of trace components within complex mixtures.\textsuperscript{(46)}

When ionizing laser fluences of the order of $10^6$ W cm$^{-2}$ are employed, soft ionization is observed. However, fragmentation has been demonstrated for fluences of the order of about $10^8$ W cm$^{-2}$. Such selective fragmentation has been used to provide structural information from detected parent ions. Tandem MS measurements have been demonstrated using a scanning reflectron approach similar to that employed during post-source decay (PSD) analysis of today’s MALDI/TOF devices.\textsuperscript{(43)}

Schlag et al. described a molecular beam MPI source coupled to a simple linear TOFMS device utilizing a 30-cm-long flight tube. This system provided unit mass resolution for compounds up to 260 $m/z$. Higher resolution was achieved for a reflectron device (3900 $m/dm$ for benzene).\textsuperscript{(45)} Zare described a linear TOF device for analyzing solid samples via MPI. Neutrals were desorbed using a pulsed CO$_2$ laser ($\lambda \sim 10.6 \mu$m) and subsequently ionized via a frequency-quadrupled Nd:YAG ($\lambda = 265$ nm) laser. This device was used for quantitative analysis of phenylthiohydantoin-conjugated amino acids.\textsuperscript{(47)} Zare’s quantitative approach was ultimately patented (US Patent No. 4988879) and was shown to be successful in the analysis of as little as 5 fmol of protoporphyrin IX, 50 fmol of $\beta$-estradiol, and 200 fmol of adenine.\textsuperscript{(47)} Lubman and Tremeurrel described a solid-phase MPI system that utilized a supersonic pulse of gas as an ion-cooling medium that greatly improved the mass resolving power of a linear multiphoton ionization/time-of-flight (MPI/TOF) system. Typical resolution of the order of about 250–300 for a number of amino acids, neuroleptic drug agents, water-soluble vitamins, and purine bases was demonstrated.\textsuperscript{(44)}

Although MPI proved to be valuable in the study of many organic and small biological compounds, it was never applied successfully to routine studies of larger biopolymers. As such, plasma desorption mass spectrometry (PDMS) and ultimately the techniques of MALDI and ESI greatly restricted the use of this approach in the arena of life science research.

Undoubtedly, the soft ionization approaches of ESI and MALDI are responsible for the recent, exponential growth in the use of TOFMS technology. ESI, first described by Fenn et al.\textsuperscript{(48)} was initially adapted to a
TOF device by Boyle and Whitehouse.\textsuperscript{(16)} An improved means of ion cooling has enabled efficient coupling of these two techniques,\textsuperscript{1,49} allowing for the availability of a number of commercial devices (see Table 1).

Two groups independently developed MALDI: the group of Tanaka and the group of Hillenkamp. In 1987, Tanaka reported the use of a colloidal matrix of cobalt powder, glycerol, ethanol, and acetone to analyze chicken egg-white lysozyme. Pseudomolecular ion clusters of 108 kDa [(7M + H)\textsuperscript{+}] were detected successfully and measured with an accuracy of better than \(\pm 1\%\) absolute error.\textsuperscript{(14,15)} This was the first reported instance where ions in excess of about 50 kDa were detected. In 1988, Karas and Hillenkamp reported the first use of an organic matrix, nicotinic acid, for the detection of proteins in excess of 10 kDa.\textsuperscript{(12,13)} Eventually, organic matrix MALDI was used to study proteins approaching 1 mDa in mass.\textsuperscript{(\textsuperscript{50})} For the most part, present-day MALDI analyses employ organic matrices and the colloidal approach has been all but abandoned. MALDI has been successful not only for the analysis of proteins and peptides, but also in the analysis of small organics, large organic polymers, oligosaccharides, oligonucleotides, as well as lipid moieties. As with ESI/TOF, a number of commercial MALDI/TOF devices exist today (see Table 1). Because the impact of ESI and MALDI has greatly affected bioanalysis and TOFMS in general, this article dedicates separate sections (sections 8.1 and 12) to describe these two techniques.

### 3 TIME-OF-FLIGHT MASS SPECTROMETRY THEORY AND FUNDAMENTAL OPERATION

The TOF mass spectrometer employs uniform, static electric fields to accelerate ions to some final velocity \(v\). Two fundamental approaches have been developed: constant-energy TOF\textsuperscript{(11)} and constant-momentum or -impulse TOF.\textsuperscript{(20)} The superiority of the constant-energy approach has eclipsed the impulse method, and all modern-day devices accelerate the ions formed to constant energy. Consequently, only theory regarding constant-energy TOF devices will be discussed.

Figure 1 depicts a single-stage ion optic, linear, constant-energy TOF mass spectrometer. Two ions \(M_1\) and \(M_2\), where \(M_2\) is heavier than \(M_1\), are accelerated to constant energy. Ion TOF is dependent upon \(m/z\), acceleration potential \(V\), acceleration distance \(s\), and free flight distance \(x\). See text for derivation.

Figure 1  A single-stage ion optic, linear, constant-energy TOF mass spectrometer. Two ions \(M_1\) and \(M_2\), where \(M_2\) is heavier than \(M_1\), are accelerated to constant energy. Ion TOF is dependent upon \(m/z\), acceleration potential \(V\), acceleration distance \(s\), and free flight distance \(x\). See text for derivation.

lens element and ground aperture. The repeller is raised to some potential \(V\) while the ground aperture is held at ground potential. If ions \(M_1\) and \(M_2\) are cations, the repeller plate is raised to some positive potential \(V\). If ions \(M_1\) and \(M_2\) are anions, the repeller plate is set to some negative potential \(V\). Only a single polarity of ions may be analyzed at any given time. In this fashion, an electric field is created between the repeller and ground aperture so that formed ions are accelerated along distance \(s\), through the opening in the ground aperture, and out into the drift tube region of the mass spectrometer. The acceleration of ions \(M_1\) and \(M_2\) within the ion optic assembly and their final velocities can be described using fundamental equations of electrostatic theory, Newtonian mechanics, and rectilinear motion.

Consider ion \(M_1\) with charge \(z\) located above the repeller plate within the ion optic assembly. If the repeller plate is raised to a potential \(V\), then the electric field strength \(E\) within the assembly is defined by Equation (5) and the ion acceleration force exerted by this field is defined by Equation (6):

\begin{equation}
E = \frac{V}{s} \tag{5}
\end{equation}

\begin{equation}
F = Ez \tag{6}
\end{equation}

From Newtonian mechanics, it is known that the force acting upon mass \(M_1\) creating an acceleration of \(a\) within electric field \(E\) can be described by Equation (7):

\begin{equation}
F = M_1a \tag{7}
\end{equation}

As shown by Equation (8), combining and rearranging Equations (6) and (7) provides an expression describing...
the acceleration of ion \( M_1 \) with charge \( z \) in field \( E \):

\[
a = \frac{Ez}{M_1} \tag{8}
\]

From the simple equations of rectilinear motion, it is known that a particle with no initial velocity achieves a final velocity \( v \) after being accelerated at a rate of \( a \) through distance \( s \) as described by Equation (9):

\[
v = \sqrt{2as} \tag{9}
\]

Substituting Equation (8) into Equation (9) yields Equation (10), which describes the final velocity of \( M_1 \) after leaving the ion optic assembly:

\[
v = \sqrt{\frac{2Ezs}{M_1}} \tag{10}
\]

Equation (10) describes \( v \) in terms of ds/dt. Consequently, the inverse of Equation (10), Equation (11), describes \( 1/v \) in terms of dt/ds:

\[
\frac{dt}{ds} = \frac{M_1^{1/2}}{2Es} \tag{11}
\]

In order to determine the TOF of ion \( M_1 \) in region \( s \), one integrates \( dt \) with respect to \( s \), yielding Equation (12):

\[
t_t = \frac{M_1^{1/2}}{2Es} 2s \tag{12}
\]

The product of the free flight distance \( x \) and Equation (11) defines the TOF for ion \( M_1 \) in the free flight region. Consequently, the total TOF \( t_t \) for \( M_1 \) is given by the sum of the latter with Equation (12), which when simplified is described by Equation (13):

\[
t_t = \frac{M_1^{1/2}}{2Es} 2s + x \tag{13}
\]

From Equation (13) it can be seen that \( t_t \) is related to \((M_1)^{1/2}\). Accordingly, ion \( M_1 \) will reach the ion detector prior to ion \( M_2 \). Equation (14) is now derived to describe the \( M_1/z \) with respect to \( t_t, E, s, \) and \( x \):

\[
\frac{M_1}{z} = \frac{t_t^2 2Es}{(2s + x)^2} \tag{14}
\]

From Equation (14), the \( M_1/z \) of any ion can be determined by measuring its total flight time once values for \( E, s, \) and \( x \) are established. For a given TOFMS system, the values of \( E, s, \) and \( x \) are intentionally held constant, reducing Equation (14) to Equation (15):

\[
\frac{M_1}{z} = kt_t^2 \tag{15}
\]

A more classical derivation of the TOF equation can be performed by examining the conservation of kinetic energy for an ion of mass \( M_1 \) and charge \( z \), traveling with final velocity \( v \) as the consequence of being accelerated through a potential difference of voltage \( V \). This derivation is appropriate for a system where free flight distance \( x \) far exceeds distance \( s \) and, as such, free flight time for ion \( M_1 \) is far greater than its acceleration period, making \( t_t \) and ion free flight time equivalent.

Newtonian mechanics describe the kinetic energy of ion \( M_1 \) traveling with a final velocity \( v \) as noted in Equation (16). Electrostatic theory equates the kinetic energy of the same particle with charge \( z \) accelerated through an electrical potential difference \( V \) as shown in Equation (17). Equations (16) and (17) are combined and rearranged in Equation (18) to describe \( M_1/z \) in terms of \( v^2 \) and \( V \):

\[
KE = \frac{mv^2}{2} \tag{16}
\]

\[
KE = \frac{Ez}{2} \tag{17}
\]

\[
\frac{M_1}{z} = \frac{2V}{v^2} \tag{18}
\]

In this simplified model, \( v \) is taken to be the quotient of distance \( x \) and flight time \( t_t \). Substituting the latter into Equation (18) yields Equation (19):

\[
\frac{M_1}{z} = \frac{2Vt_t^2}{x^2} \tag{19}
\]

For a given TOFMS system, the values of \( V \) and \( x \) are held constant, thus reducing Equation (19) to Equation (15).

From Equation (15), it can be seen that the \( m/z \) of any ion can be determined by measuring its flight time, once a value for the constant \( k \) is derived. Determining \( k \) for a TOFMS system is referred to as calibrating the mass spectrometer. Calibration is achieved by measuring the flight time for a number of well-characterized analytes and reconciling this time with established \( m/z \) values. For the most part, a least-squares-fit algorithm is applied to determine slope and intercept values for the linear relationship between \( m/z \) and the square of total flight time. A calibration expression similar to that of Equation (20) is subsequently used to determine the \( m/z \) for all unknown samples:

\[
\frac{m}{z} = at_t^2 \pm b \tag{20}
\]

Two calibration strategies are typically employed: internal standard and external standard calibration. An internal standard calibration approach spikes the sample of interest with at least one and usually a plurality of calibrants. In this fashion, the resultant spectrum from this measurement is calibrated using known \( m/z \) values for each calibrant, and a highly accurate \( m/z \) determination for the unknown is created. External
calibration experiments are performed when calibrants and unknowns are analyzed in independent experiments. The calibration function derived during the calibration experiment is applied to the unknown spectrum to provide a determination of \( m/z \).

Because slight variations in \( V, s, \) and \( x \) will occur from measurement to measurement and from sample to sample, internal standard calibration experiments typically provide about 10–100-fold improvement in mass accuracy compared to external standard approaches. However, the addition of calibrants to an unknown sample matrix is often plagued with difficulties. In some instances, the ion formation potential of the added calibrants may exceed that of the unknowns, producing significant suppression in the formation of unknown ions, thus squelching the detection of the desired samples. In other cases, similar or identical \( m/z \) for unknown and calibrant species may result in the masking of unknown signals. The latter two are particularly troublesome for TOFMS approaches that do not employ an upstream chromatographic or sample separation scheme such as laser desorption/ionization/time-of-flight (LDI/TOF) and TOFSIMS experiments. Because of the difficulties of applying internal standard calibration approaches, external standard measurements are employed most routinely.

4 TIME-OF-FLIGHT MASS SPECTROMETRY INTERFACE CONFIGURATIONS, ION EXTRACTION GEOMETRIES, AND OPERATIONAL SCHEMES

4.1 Interface Configurations

Interface configurations for the TOF mass spectrometer are typically dependent upon sample inlet system requirements, sample ionization means, as well as sample extraction and mass analyzer geometries. Inlet system and ionization source requirements are often tightly coupled. For the most part, the state of the sample (gas, solid, liquid) and its means of introduction dictate inlet system and ionization specifics.

In many instances, the TOF device serves as a MW detector for some upstream chromatographic scheme such as GC, high-performance liquid chromatography (HPLC), CE, and CEC. In this fashion, a dynamic interface supporting continuous-flow sample introduction is utilized along with an appropriate ionization source. In the case of GC, modern devices couple a continuous-flow gas interface with EI, CI, metastable atom bombardment (MAB), or supersonic molecular beam (SMB) ionization sources. For LC, CE, and CEC, an atmospheric-pressure, liquid-phase interface is coupled with primarily ESI or CI sources.

Static sample introduction of solid-state and liquid analytes is typically achieved using a solid probe interface. The probe can be a simple, single-position device capable of rotation or it can be a more complex multiposition device capable of rotational, rectilinear, or two-dimensional (linear–linear, or circular–linear) movement. Such interfaces are typically employed with LDI, MALDI, surface-enhanced laser desorption/ionization (SELDI), PD, and SIMS sources.

4.2 Ion Extraction Geometries: Parallel Ion Extraction

Presently, TOF devices use one of two fundamental schemes of ion extraction: parallel ion extraction and orthogonal ion extraction. Static sample interface systems typically utilize parallel ion extraction. A parallel ion extraction LDI device is depicted in Figure 2. In this example, the energy inherent in a short-duration laser pulse creates ions in a well-defined region immediately above a solid probe. In this case, the solid probe is contiguous with the repeller lens of the ion optic assembly. In some instances, such as with two-dimensional sample stages, the solid probe is the repeller. In contrast to the simple ion optic assembly of Figure 1, the assembly of Figure 2 is a dual-stage design containing an additional plate known as an extractor. During ion acceleration, the extractor potential is established to be less than that of the repeller and greater than that of ground.

For this geometry, ion extraction can be performed in a continuous or pulsed manner. In the case of continuous ion extraction (CIE), ions are formed in the presence of an accelerating field created by the potential drop between repeller and extractor elements, tightly coupling ion formation with ion extraction. In PIE, ions form in an equipotential region created by holding the repeller and extractor lenses at the same voltage. Ions are subsequently extracted by the application of a high-voltage pulse, which either raises the repeller or lowers the extractor potential, creating an accelerating electrical field.

Extracted ions are further accelerated between the extractor and ground lens elements and ultimately enter the free flight region. In some devices, emitted ions enter a short free flight region located between the ion optic assembly and an ion deflector, where they begin to separate out in time and space as dictated by their \( m/z \)-dependent final velocities. The ion deflector of Figure 2 incorporates a time-based, pulsed, orthogonal, electrostatic acceleration field, which perturbs the trajectory of all ions that enter it when the pulse is applied. In this manner, ions of little interest can be deflected from striking the ion detector. As will be explained further, the latter improves detector sensitivity and signal baseline stability. The pulse is shut off to allow all other ions ultimately to strike the detector.
Ions striking the detector are converted to electrons and the subsequent current creates an electrical potential that is digitized by a high-speed, time-array recording device that digitally captures the entire analog signal of each TOF cycle. Time-array recording devices include waveform (or transient) recorders, analog-to-digital converters (ADCs), and digital oscilloscopes. In many cases, digitization is provided by a high-speed ADC. The ADC transfers digital information to a data reduction software package, which provides visualization and higher order processing of the ion signal. Resolved ion populations are typically represented as a peak whose intensity and area are related to abundance, and flight time is related to \( m/z \).

Flight time measurement is performed by the high-speed ADC. After receiving a start trigger, the ADC integrates detector output voltage at regular time intervals. Arrival of the ADC start signal is coordinated with the onset of ion extraction. For CIE systems, the start signal is tightly coupled to the point of ion creation. In Figure 2, an optical beam splitter is employed to direct a small portion of the laser beam to strike a trigger photodiode that serves as a lasing event detector. The lasing event signal (photodiode solid lines) provides the ADC start trigger for CIE analyses. For PIE approaches, the lasing event signal (interrupted line) provides a start trigger for a time-delay generator, which, after a pre-established time period, provides a start trigger to a pulsed high-voltage ion extractor. Coincident with the applied ion extraction pulse, the high-voltage ion extractor provides a start signal to the ADC.

After receipt of the start trigger, the ADC sorts integrated detector voltage values into discrete time-dependent bins. Each bin possesses a finite level of time resolution that is dependent upon the data acquisition rate (DAR) of the ADC. For the most part, ADCs with 500–2000 megasample s\(^{-1}\) acquisition rates are employed, providing a temporal resolution of 2000–500 ps per data point. ADC data storage continues for a scan period that is defined by the TOF of the heaviest ion of interest. It is not unusual to see scan periods of the order of 200 µs, requiring about 400 kbytes of memory for a 2000 megasample s\(^{-1}\) DAR.

Because the majority of ions formed are extracted in every scan and because an ADC takes data at every scan-period time bin, parallel extraction approaches can provide a complete mass spectrum after a single scan. However, it is common practice to sum a number of scans together to improve the overall signal-to-noise ratio (S/N) for the resultant spectrum. Furthermore, geographical heterogeneity of solid-state samples frequently requires the interrogation of different regions to provide complete ion profiles. Consequently, single-scan spectra are rarely compiled.

Scan rates of parallel extraction devices are basically limited by the ion source duty cycle and sample movement time. In the case of LDI, repetition rates are of the order of 5–20 lasing events per second and fine sample movement is achieved in about 300 ms. A quality spectrum is generally produced after the summing of 20–50 scans, resulting in an effective spectral acquisition time of about 1–30 s.
4.3 Orthogonal Ion Extraction

Orthogonal extraction geometries are generally used with dynamic or continuous-flow interfaces. Historically, this geometry has been coupled with EI analysis of cold molecular beams as well as atmospheric-pressure plasma ion sources. More recently, these approaches have been coupled with ESI and MALDI.

Figure 3 illustrates a typical orthogonal extraction TOF device coupled with a continuous-flow interface. Unlike the linear, parallel extraction geometry of Figure 2, this analyzer uses an ion mirror or reflectron to provide improved mass resolving power. The specifics of this process will be discussed later.

Ions enter the TOF analyzer by traveling through an ion guide assembly. For the most part, these ion guides are multipolar RF devices usually consisting of four or eight cylindrical rods. A four-pole array is known as a quadrupole assembly and an eight-pole configuration is referred to as an octopole assembly. A potential well is created within the center of this guide that functions to constrain ion radial trajectory, thus minimizing radial ion spread. Ions travel through the length of the guide by primarily relying upon their nascent velocities and secondarily assisted by accelerating electrical fields and pressure drops. As ions travel through the guide, they undergo a series of collisions with background gas. These collisions function to dampen the initial energy of these ions to a point that approximates to that of their thermal state, almost eliminating their radial velocity, while slowing their axial velocities down to the order of 25 m s\(^{-1}\). As will be explained later, the latter is essential to provide reasonable mass resolving power.

A dampened, collimated ion beam enters a field-free region of the ion optic defined between the repeller and extractor plates. When this region becomes filled with ions, the potential of the repeller plate is elevated through the use of a high-voltage pulser, and the ions are ejected out of the optic assembly and into the free flight region. Ions enter the ion mirror and then are turned about to strike a detector.

The ultimate rate at which ions are extracted is dependent upon a balance that is struck between the flight time of the heaviest ion and the time required for all ions to enter and not overfill the extraction region. Should the required flight time exceed that of the fill-up time of the extraction region, the instrument’s duty cycle is effectively reduced and sensitivity suffers. For the most part, ions are extracted at rates of \(10^4 – 10^5\) cycles per second. In many instances, these extraction rates significantly exceed the rate of ion introduction, dividing the introduced ion load into a number of low-ion-density TOF scans. Resultant TOF scans typically contain less than one ion per injection pulse per ion species. This is in stark contrast to parallel extraction, where many ions for a given species are introduced in every scan.

In most orthogonal extraction TOF spectrometers, a high-speed, time-interval-recording device such as a time-to-digital converter (TDC) measures ion TOF. Unlike time-array devices, a TDC is an individual pulse-counting mechanism that records the detector signal over a finite time span. The recording event is followed by a dead time period when the TDC remains refractory to any further pulse counting. Only a single impulse is stored in each time bin. Typical time bin resolution is of the order of hundreds of picoseconds, whereas dead time periods exist for a few nanoseconds. Considering the...
latter, it becomes clear that true waveform reproduction is solely possible when only a single ion is present for each counting period. Furthermore, a single TOF scan does not produce a complete spectrum. Consequently, many thousand of scans must be acquired to provide a spectrum that accurately reflects the true ion population.

Triggering the TDC is generally accomplished by the high-voltage ion pulser, thus establishing the beginning of the TOF cycle at the point of ion extraction. Pulse counting occurs when detector output voltage exceeds a pre-established level of discrimination. This is followed by a dead period, after which the cycle repeats. Several ion counts are performed for each scan. Many scans are summed within the TDC prior to transfer to the system computer, where signal-reduction software ultimately provides visualization and higher order processing of the ion profiles.

For a given chromatographic or static analysis, total spectral acquisition time for this approach is dependent upon mass range and sensitivity requirements. With increasing mass range, some systems suffer duty cycle loss, requiring greater scan numbers. For trace analysis, large scan numbers are also needed. The rate of data transfer from the TDC to the data-reducing computer also plays a limiting role. For the most part, quality spectra are produced within a few seconds of time. In the extreme case of trace analysis and/or extended mass range, acquisition times may approach 30–60 s. Obviously, the latter becomes obviating in terms of high-resolution chromatographic techniques. Consequently, most continuous-flow, trace analysis approaches avoid upstream chromatography and resort to flow introduction of a cleaned up or homogeneous sample.

5 FACTORS AFFECTING PERFORMANCE IN TIME-OF-FLIGHT MASS SPECTROMETRY

5.1 Mass Accuracy

As is the case with many other analytical methods, fundamental performance in TOFMS is described in terms of system accuracy, resolving power, and sensitivity. TOFMS devices measure the fundamental mass-to-charge ratio \(m/z\) of an ion. Ion \(m/z\) is defined by Equation (21), where \(A_{\text{mw}}\) is analyte MW, \(C_{s\text{mw}}\) is the total MW of added or deleted charging species, and \(cs\) is the total charge of all charging species:

\[
\frac{m}{z} = \frac{A_{\text{mw}} \pm \sum C_{s\text{mw}}}{\sum cs} \tag{21}
\]

Once the nature of an ion’s charge is established, analyte MW is easily determined. In most cases, cations are created by the addition of a proton (H\(^+\)), a metal (Na\(^+\), K\(^+\), Ag\(^+\), etc.), or the loss of an electron. Anions usually arise by the loss of a proton or the addition of an electron. It is common to ignore electron mass when determining analyte MW.

The metric of mass accuracy is often discussed in terms of error with respect to analyte true mass. Error is usually reported as an absolute difference in \(m/z\) or MW (Da), or as a fractional error with respect to true MW (percent error or parts per million). To understand the sources of mass measurement error in TOFMS, it is best to re-examine the fundamental TOF expression as described by Equation (14) for the TOF arrangement of Figure 1.

Equation (14) describes the determined \(m/z\) of ions with charge \(z\) and total kinetic energy that is entirely dependent upon acceleration within the ion optic assembly. In this simplified case, all ions are assumed to form at the same time, at the same ion optic location, with no initial kinetic energy. In reality, this is rarely the case and most ion populations demonstrate some variance in initial position, time of formation, and possess some initial kinetic energy \(U_o\). Considering the latter, Equation (14) must be modified to account for \(U_o\), yielding Equation (22), where \(E\) is ion acceleration field strength, \(s\) is the distance through which an ion is accelerated, \(x\) is ion free flight distance, and \(t_i\) is total ion flight time:

\[
\frac{m}{z} = \left[(2Es + U_o)(2s + x)^{-2}\right]t_i^2 \tag{22}
\]

Rearranging Equation (5) in terms of applied voltage and substituting this into Equation (22) yields Equation (23), where \(V\) is the voltage applied to the repeller (see Figure 1):

\[
\frac{m}{z} = \left[(2V + U_o)(2s + x)^{-2}\right]t_i^2 \tag{23}
\]

In most TOF systems, design approaches are taken to minimize variation in \(V\), \(s\), and \(x\), thus reducing Equation (23) to Equation (15), and enabling simple calibration of the system as noted by Equation (20). During actual practice, system warm-up time and ambient temperature conditions often result in high voltage instability and subtle shifts in ion acceleration and free flight distances. Furthermore, changes in sample introduction conditions, such as ion phase space and solid crystal size or film thickness, create notable alterations of ion acceleration distance. Likewise, variations in the position of ion formation create changes in both \(s\) and \(x\), and variations in time of ion creation or onset of TOF measurement create ambiguities in \(t_i\). All of these factors combine to perturb the consistency of \(V\), \(s\), \(x\), and \(t_i\), resulting in attendant mass assignment error.

Variation in \(U_o\) is another source of mass assignment error. If \(U_o\) increases, total kinetic energy increases...
and the resultant TOF for a given ion will accordingly decrease, creating a lighter than actual MW determination. Should $U_0$ decrease, the opposite occurs. Because of the random, combinatorial effects of changes in $V$, $s$, $x$, $t_t$, and $U_0$, internal standard measurements generally provide greater mass accuracy than external standard approaches.

A special consideration of $U_0$ and mass assignment accuracy occurs if $U_0$ is not constant for all $m/z$. This condition violates the assumptions for Equations (22) and (23) and thus the simple linear relationship of calibration (Equation 20) no longer applies. Such a condition has been reported for MALDI/TOF experiments with both CE and PIE. Zhou reported the existence of an energy deficit between low-molecular-weight ions and higher-molecular-weight ions as studied by MALDI with CE. In this instance the $U_0$ of some proteins and peptides in the range 1–12 kDa was found to decrease with increasing MW. Nelson reported a trend of increasing $U_0$ with analyte MW while analyzing human IgM (MW $\sim$ 980 kDa) using MALDI/TOF with CE. Unpublished results obtained by this author on the study of a number of proteins in the range 6–100 kDa using MALDI/TOF with CE and PIE agreed with the findings of Nelson. This apparent increase in $U_0$ as a function of increasing MW may be explained by considering the initial desorption velocities ($V_0$) of MALDI-formed ions.

Several studies of $V_0$ for MALDI-formed ions have been performed. Although discrepancies exist in terms of the absolute value of $V_0$, a common trend of decreasing $V_0$ with increasing analyte MW is reported. Furthermore, average ion $V_0$ has been demonstrated asymptotically to reach a minimum value at some ultimate $m/z$. Consequently, ion $U_0$ as dictated by a constant $V_0$ would increase with increasing MW as predicted by Equation (16).

Figure 4 depicts the effect of $U_0$ upon mass calibration by plotting analyte MW against the square of ion flight time. Two major populations of ions are illustrated: $m/z < 200$ kDa and $m/z > 400$ kDa. A second-order-fit line is easily driven through all points. Clearly, the simple, linear relationship between $m/z$ and the square of ion flight time does not apply. If a simple linear fit were employed to calibrate the system using the first several points of the 200-kDa group, the function depicted by the low-MW calibration line would result. Applying this low-MW calibration function to the measurement of ions in excess of 200 kDa would result in determined MWs that are less than their actual values. In a similar manner, if calibration was performed using the last several points of the >400-kDa group, a calibration function as depicted by the high-MW calibration line would result. If low-MW ions were analyzed using the high-MW calibration expression, measured MWs would again be less than their actual values.

![Figure 4](image-url)  
*Figure 4* The effect of ion initial kinetic energy ($U_0$) on the linearity of the TOF calibration expression and mass determination accuracy is presented. In this plot, ion TOF was calculated based upon 30-kV acceleration, $V_0 = 350 \text{ m/s}$, and 1-m free flight. The trend is carried out to 1.2 mDa for demonstrative purposes.
As demonstrated, non-linearity of the TOF equation will result in additional mass assignment error whenever measurements are performed outside the m/z limits of the calibration experiment and extrapolated MWs are determined. This applies to both internal and external standard approaches. Although it is possible to correct for this nonlinearity by using higher order fits, accurate MW determination for large ions remains dependent upon calibrating against a well-characterized standard in the high-MW domain. In reality this approach is problematic, because very few well-characterized calibrants with MWs in excess of 70 kDa are readily available today.

An instrumental means to address this problem was taken by Whittal et al. This approach, known as functional wave TLF, employed an ion extraction pulse for which a time-dependent change in extraction field strength (E) was applied in a manner to compensate for differences between light and heavy ions. At the beginning of the ion extraction cycle, E is held at its maximum value. As ions are accelerated out of the extraction region, the value of E decreases. In this manner, ion total acceleration will be dependent upon m/z and the integral of the wavefunction for E during the ion extraction period. Because lighter ions leave the extraction region before heavier ions, they receive a greater degree of acceleration when compared to their heavier counterparts. A functional wave pulse is selected to provide a mass-dependent difference in total ion acceleration that compensates for differences in Uo between light and heavy ion species, allowing for the use of simple, linear-fit calibration expressions. A 10–20-fold improvement for linear-fit, internal standard mass assignments for several proteins in the range 5.7–29 kDa was demonstrated for the functional wave pulse system when compared to the conventional pulsed ion approach of TLF.

The overall affects of varying initial ion position, ion time of formation, and ion Uo upon mass accuracy is dependent upon ion extraction geometry. For the arguments presented above, parallel ion extraction geometry is assumed. In the case of modern orthogonal extraction, collisional cooling minimizes ion radial Uo disparities that would deleteriously affect total kinetic energy in the direction of TOF measurement. Furthermore, any change of initial ion axial velocity does not affect total ion flight time in the orthogonal direction. In this fashion, the effects of ion Uo are greatly removed from producing mass assignment error. Because ions are created downstream, often requiring 1–2 ms to enter an orthogonal extraction region, final ion TOF becomes independent of the original time or location of ion formation. However, within the ion extraction and free flight regions, mass accuracy in orthogonal TOF devices remains affected by variations in ion acceleration voltage, as well as variations in ion acceleration and free flight distances.

Dependant upon ion source and ion extraction geometries, today’s state-of-the-art TOF devices provide typical mass accuracy of the order of 1–10 ppm for internal standard measurements and 20–200 ppm for external standard approaches. Because initial ion position, ion time of formation, and ion Uo are uncoupled from total ion flight time in orthogonal TOF, orthogonal devices typically provide superior external standard mass accuracy when compared to parallel extraction systems.

5.2 Resolution

Resolution is basically the ability to detect subtle differences in m/z among different ion populations. Several mathematical models and definitions of resolution have been suggested. For the most part, TOF mass resolving power has been defined by Equation (24), where m is the determined mass of an ion, T is ion TOF, dm is the width (in Da) of the measured peak at half-magnitude, and dT is the half-height-measured peak width in time:

\[
R = \frac{m}{dm} = \frac{T}{2dT} \tag{24}
\]

Equation (24) may be derived by first rearranging Equation (15) in terms of \( M_1 \) to yield Equation (25). Taking the derivative of \( M_1 \) in Equation (25) with respect to \( t_r \) yields Equation (26). Dividing Equation (25) by Equation (26) yields Equation (24).

\[
M_1 = z_k r_t^2 \tag{25}
\]

\[
dM_1 = z_k 2r_t \, dt_r \tag{26}
\]

![Figure 5](image_url) MALDI/TOF analysis of substance P, neurotensin, and dynorphin A. An expanded view of neurotensin is provided, demonstrating the fwhm and resultant resolution of about 6000 m/dm. (Figure adapted from data provided by Dr Robert Brown, Utah State University.)
Figure 5 depicts a MALDI/TOFMS analysis for a mixture of peptides. The neurotensin signal is expanded to reveal the individual isotopic populations. In this figure, the full width at half-maximum (fwhm) of the $^{13}$C peak is indicated. The resolution of this signal was determined to be roughly 6000 $m/dm$.

The interdependency of mass accuracy and mass resolving power has been known for some time. In the 1960s, Campbell and Halliday showed that the standard deviation of mass measurement is related to signal resolution and the number of ions detected for a given deviation of mass measurement is related to signal strength. When resolution is extremely high, single-isotope ion populations are detected with good counting statistics and ion TOF is easily determined as the apex of a symmetrical peak. When resolution suffers, isotope discrimination becomes limited, and the introduction of peak asymmetry from convoluted isotopic envelopes as well as distortion due to poor ion counting statistics skew the true mass from the peak’s apex. In order to compensate for these effects, ion TOF is generally estimated using some form of moment analysis. Gaussian or Lorentzian algorithms are often applied to determine the centroid of the measured signals. These centroid TOF values are subsequently used to determine $m/z$.

Factors affecting TOF resolution are associated with the initial conditions of ion formation and acceleration, free flight perturbations, as well as instrumental limitations. Figure 6 demonstrates the effect of various parameters of initial ion formation upon time spread for a homogeneous population of ions constantly extracted by a parallel electrical field. The upper panel describes a system in which all ions are introduced at the same location at the same time, with the same initial speed and equivalent energies. However, initial ion directions of travel are different. Consequently the initial velocities of these ions ($V_o$) with respect to the plane of detection are different, as indicated by $V_1$, $V_2$, and $V_3$. Ion optic acceleration and focusing of these ions drive all species toward the detection plane. Ion final velocity is the vector sum of ion $V_o$ and imparted velocity due to electrostatic acceleration. Because of the latter, these three ions achieve different final velocities and strike the detector at different times where the TOF of $V_1 < V_3 < V_2$. In this particular case, mass resolving power is limited by the spread of $V_o$ and cannot be improved by lengthening free flight. Resolution may only be enhanced by methods that compensate for differences in $V_o$ by using differential acceleration or by those that provide different free flight distances for ions of different final velocities.

The second panel displays a system in which all ions are created at the same time, in the same location, with different speeds traveling in identical directions. In this manner, these ions have different initial energies $U_o$, created by differing $V_o$. All ions are identically accelerated to different final velocities, creating a resolution-limiting, ion arrival time spread at the detection plane. As in the first panel, resolution may only be enhanced by methods that compensate for $\delta V_o$ and $\delta U_o$.

The third panel illustrates a condition where all ions are formed at the same time, with identical $V_o$ and $U_o$ at different locations. In this instance, these ions vary in final velocity ($v$) (and final energy) because the acceleration that each ion receives is different. As predicted by Equation (10), ions closer to the repeller are accelerated to greater $v$ than those located away from the repeller. Although initial ion positions place $S_1$ as being the closest to the detector, followed by $S_3$ and $S_2$, differential acceleration of these ions creates final TOF profiles for which $S_2$ arrives at the detector first, followed by $S_3$ and then $S_1$. In this example, resolution is limited by the initial spatial distribution of all ions formed and cannot be corrected by lengthening the free flight. However, spatial spread may be corrected by applying an appropriate degree of differential acceleration so that all ions are temporally coincident upon the detection plane.

The lower panel depicts a scenario in which all ions are formed in the presence of an accelerating field at the same location, with equal $U_o$ and $V_o$, but at different times. Here all ions are accelerated to identical final velocities, but a fixed time spread defined by the $\delta T$ of ion formation will be maintained throughout the TOF period. In this case, lengthening of the free flight distance may enhance resolution.

Because it is customary to sum several TOF scans to create a given spectrum, there is an additive effect upon...
the uncertainties in $V_o$, $U_o$, $S_o$, and $T_o$. All of these variances add in quadrature, and they must be minimized to preserve mass resolving power.

When ions leave the ion optic and enter the free flight region, collisions with background gas result in momentum transfer processes that ultimately alter ion final velocity. In this fashion a time-focused, homogeneous population of ions will exhibit time spread as a direct consequence of such collisions. This effect is illustrated in Figure 7. As analyzer region pressure decreases, resolution in the MALDI/TOF analysis of human insulin, equine cardiac cytochrome c, and BSA improves. Schuerch et al. reported similar results for the MALDI/TOF analysis of poly(ethylene glycol) 4000.$^{73}$ Generally speaking, acceptable TOF resolution is achieved for free flight pressures in the range $10^{-7}$–$10^{-8}$ Torr.

Instrumental limitations also play a governing role in mass resolving power. Any condition that results in instability of ion acceleration, such as variance in high-voltage power supply regulation or collapse of ion acceleration fields, creates accompanying shifts of ion flight time. Furthermore, irregularity in the onset of the TOF measurement cycle with respect to ion acceleration also produces ambiguities in TOF. Because a number of TOF scans are generally summed to create spectra, these factors randomly combine to widen measured peak widths and to limit resolution.

Aside from instrumental instabilities, fundamental instrument properties such as free flight distance, total ion acceleration energy, DAR, and detector system analog bandwidth also affect mass resolving power. Figure 8 demonstrates the effect of free flight distance and ion total kinetic energy upon the change in TOF ($\delta t$) with respect to the change in MW ($\delta m$). As free flight distance decreases and total kinetic energy increases, $\delta t/\delta m$ decreases and a greater DAR and broader analog bandwidth is required to preserve mass resolving power. It is noteworthy to discuss the effect of these factors on the resolution of a small peptide with MW $1000$ Da. In order to maintain unit mass resolution, a system utilizing $30$ kV of acceleration and $0.33$ m of free flight would require a $1$-gHz detector bandwidth and must digitize at more than three gigasamples per second (330 ps time resolution). Similarly, a system using $15$ kV acceleration and $1$ m of free flight would require about a $300$-mHz bandwidth and a one gigasample per second DAR.

![Figure 7](image_url) Resolution for the MALDI/TOF analysis of human insulin (h,r-Insulin), equine cardiac cytochrome c (Eq. C. Cytochrome c) and bovine serum albumin (BSA) is plotted as a function of free flight pressure. See text for further details. (Unpublished data from Scot R. Weinberger.)

![Figure 8](image_url) Analyte TOF vs MW for 15 and 30 keV of final energy and 1.0, 0.5, and 0.33 m free flight. As total energy increases and flight tube length decreases, $\delta t/\delta m$ decreases, placing a greater burden upon digitizing speed and analog bandwidth.

![Figure 9](image_url) The effect of DAR on the resolution of bovine insulin. (Figure adapted from data courtesy of Bruker Daltonics, Billerica, MA, USA.)
Figure 9 further demonstrates the resolution effects of DAR. In this example, bovine insulin is analyzed using constant acceleration potential, free flight distance, and analog bandwidth but employing two different digitizing rates: one and four gigasamples per second. Ostensible differences in resolution are demonstrated between the one and four gigasample per second DARs.

From first principles it has been demonstrated that, for a given amount of initial energy spread, resolution improves with increasing ion acceleration potential. Although this is certainly true, it is important to note the interactive impact of total kinetic energy, free flight distance, and DAR upon resolution. Figure 10 demonstrates the effect of total kinetic energy upon resolution for MALDI/TOF analysis with CE of human insulin, bradykinin, and the pentapeptide VPDPR (valine-proline-aspartic acid-proline-arginine). As acceleration potential is increased from 10 to 20 kV, the observed resolution for all three compounds improves. However, when acceleration potential is further increased, improved resolution is noted only for insulin. In this case, the additional acceleration has narrowed the bradykinin and VPDPR peak widths to a point where the system’s analog bandwidth and DAR effectively limit them. As acceleration potential increases, TOF decreases but peak widths remain fixed at the data system limit. The end result is a reduction in mass resolving power. In this instance, increasing free flight distance would meliorate this effect.

As can be seen, optimizing the resolution often requires a compromise between system free flight distance, ion acceleration potential, system analog restrictions, and DAR. As will be demonstrated later, TOFMS detection sensitivity is related to ion total kinetic energy. As such, most useful TOF devices accelerate ions to at least 20 keV of total energy. Considering the latter, small, footprint devices should use broad-bandwidth, high-speed data acquisition systems to provide adequate mass resolving power and mass accuracy. Large, research-grade instruments combine 2–3-m-long free flight regions with high-energy acceleration and high-performance data acquisition systems to provide mass resolving power in excess of 10 000 m/ dm and associated mass accuracy in the low parts-per-million range.

6 ION FOCUSING MEANS TO IMPROVE RESOLUTION

The deleterious effects of energy, spatial, and time spread of ion creation upon mass resolving power became painfully clear to many early TOF pioneers. The resolving power of early devices was significantly limited by energy and spatial variations. For many years, the TOF mass spectrometer had a reputation for providing poor resolution, greatly restricting its applicability and further fueling the growth of other MS approaches. Eventually, several energy and spatial focusing techniques were developed, ultimately improving the mass resolving power in TOFMS. This section reviews these solutions.

6.1 Time-lag Focusing

Perhaps the most significant development in improving resolution in TOFMS came in 1955, when Wiley and McLaren introduced the concept of TLF. Wiley and McLaren mathematically derived expressions describing ion flight time in a linear TOF device using a dual-stage ion optic assembly and an EI source. They separately considered the effects of spatial and energy aberrations upon mass resolving power. In terms of spatial variance, the optimal resolving power of a system exhibiting a maximum spatial spread of $\Delta s$ was shown to be described by Equation (27), where $M_s$ is the spatial-spread-limited maximum resolution, $s_o$ is average initial ion position, and $k_o$ is an instrumental constant:

$$M_s \approx 16k_o \frac{s_o^2}{\Delta s}$$

In the case of no spatial spread, they noted the maximum resolving power ($M_s$) of a device with an initial energy spread of $U_o$ and total kinetic energy of $U_t$ to be described
Wiley and McLaren conceived the concept of energy or spatial TLF to correct for variations in initial ion energy or position. Let us consider the case of energy TLF. PIE is employed and ion formation and acceleration become uncoupled (see Figure 11). In the first phase of TLF – the lag period – ions are created in a field-free region and are allowed to drift to final positions that are dependent upon their nascent velocities. Upon completion of the lag period, an ion extraction pulse is applied to either increase the potential of the repeller or decrease the potential of the extractor, thus creating an accelerating electrical field. At the time of extraction, ions have drifted to some final position that is correlated to their initial velocities. Ions closest to the repeller – the lagging group – are accelerated through a greater extraction (ext.) potential difference than those further away – the leading group. The parameters of lag time and pulse voltage are selected so that lagging ions catch up with leading ions at some image plane. In most cases, the image plane is the point of ion detection.

Energy TLF conditions are determined by taking the derivative of the total ion flight time ($T$) with respect to initial energy ($dT/dU_o$) and solving for the condition where $dT/dU_o$ is zero. The optimal lag for a given ion using a pulse voltage of $V_p$ is described by Equation (30),

\[
t_L \propto s \left( \frac{m}{z} V_p^{1/2} \right) \left( \frac{1}{k} + \frac{U_o}{V_p} \right)^{1/2}
\]

Space focusing conditions are similarly arrived at by taking the derivative of total ion flight time with respect to initial ion position ($s$) and solving for the condition where $dT/ds$ is zero. When this is done, Equation (31) is derived, where $D$ is the point of ion focus, $s_o$ is average initial ion position, $k_o$ is the instrument constant of Equations (27) and (28), and $d$ is the acceleration distance of the ion optic second stage (see Figure 11). As can be seen, this focus condition is the same for all ions and is independent of the total energy of the system.

\[
D = 2s_o k_o^{1/2} \frac{1 - d}{(k + k^{1/2})s_o}
\]
constraints (ion optic subsequent acceleration and total free flight distance) the required pulse voltage for energy focusing is directly proportional to \( m/z \). Conversely, under the same assumptions, the required lag time of a constant ion ejection pulse is related to the square root of \( m/z \).

TLF has been applied to a variety of ionization schemes, including laser desorption,\(^\text{75}\) MALDI,\(^{76}\) MALDI,\(^{74,77–83}\) and orthogonal TOF geometries.\(^{54–58}\) In the case of MALDI/TOF, TLF has been referred to as delayed extraction, delayed ion extraction, dynamic extraction, and space velocity correlation focusing. The addition of TLF to MALDI analyses has resulted in significant improvements in mass resolving power, mass accuracy, and analytical sensitivity. Uncoupling MALDI ion creation from ion acceleration has resulted in softer extraction of analyte ions from dense clouds of matrix ions and neutrals. In this manner, collisions between parent ions and matrix products are minimized, decreasing energy dispersion as well as fragmentation of analyte ions during the extraction process. The result is a more narrower energy distribution and marked reduction of chemical noise.\(^{81}\) An additional benefit of TLF and MALDI is the ability to obtain structural information from prompt fragmentation.\(^{77}\) This technique, known as in-source decay (ISD) analysis, will be discussed further in section 14.2.

The addition of TLF to continuous-flow liquid- and gas-phase TOF devices has significantly improved TOF resolution, mass accuracy, and overall utility as a chromatographic detector. In this application, TLF corrects for a spatial distribution prior to analysis in an orthogonal, reflecting TOF analyzer.

### 6.2 Post-source Pulse Focusing

Although TLF provides enhanced resolution for a restricted mass range in linear systems suffering from \( U_0 \) dispersion, under some conditions it may actually create defocusing of signals outside of the \( m/z \) range of enhancement. Because of the latter, several researchers suggested the use of post-source pulse focusing (PSPF) as a means of improving resolution.\(^{84–89}\) In this approach, CIE is employed and ions are accelerated to enter a PSPF region. The PSPF region is either the last stage of an ion optic or a discrete assembly segregated from the source ion optic by a short free flight region. In a manner analogous to TLF, a discrete packet of ions enters the PSPF region with an inherent final velocity spread. At first, the PSPF region is acceleration field free. When focusing is desired, a high-voltage pulse is applied to create a post-source acceleration field. Differential acceleration proceeds with lagging ions receiving a greater degree of acceleration than their leading counterparts.

The amplitude of the pulse potential is chosen so that lagging ions catch the leading ions at the system's detector. The advantage of this approach, when compared to TLF, is that one can select an \( m/z \) range for focusing without defocusing other ions. When the focusing pulse is not applied, all other ions pass through the PSPF region without subsequent acceleration. However, because the focused ions have received a different degree of acceleration when compared to all other ions, they now have a different amount of kinetic energy. Consequently, these ions require a different calibration expression for \( m/z \) determination to that for unfocused ions. Higher order calibration expressions have been derived to determine the \( m/z \) of PSPF ions but these algorithms are not simultaneously applicable to unfocused ions.\(^{88,89}\)

In the final analysis, PSPF effectively enhances resolution and mass accuracy for a limited \( m/z \) range in linear TOF devices. Because PSPF employs CIE, the advantages of decoupling ion formation from acceleration are not realized. Furthermore, because PSPF acceleration occurs at an appreciable time after ion formation, a greater amount of metastable decay products are present at the time of differential acceleration, increasing the overall chemical noise. Because of these issues, the use of TLF over PSPF in linear geometries is generally favored.

### 6.3 Dynamic Pulse Focusing

Other attempts at extending the \( m/z \) focusing range to enhance mass accuracy and resolution have concentrated upon altering the nature of the ion extraction pulse. In classical TLF, a square-wave extraction pulse is applied to the energy-focusing region of an ion optic assembly. In this manner, a constant-focusing field is applied to ions of all \( m/z \) and some ions become focused but others are not. Dynamic pulse focusing takes advantage of the different residence times of ions of varying \( m/z \) within the energy-focusing ion optic region. These approaches apply a time-dependent extraction pulse in order to focus more appropriately the ions over a broader \( m/z \) range.

In 1974, Marable and Sanzone discussed the use of an impulse field focusing approach for which a time-dependent change in ion extraction field strength could be employed to extend the focusing range of an electron ionization/time-of-flight (EI/TOF) device out to 2600 \( m/z \).\(^{90}\) They later reduced this theory to practice in 1981.\(^{91}\) In this device a two-step ion draw-out field was used. Although the mass range of resolution enhancement was increased, optimization was still shown to be \( m/z \) dependent.

Muga described a system that used a second-order time-dependent post-acceleration field in the second stage of a two-stage ion optic assembly. CIE acceleration was
performed in the first stage. This device showed unit mass resolution for EI/TOF analysis out to 4000 \( m/z \).\(^{92}\)

As discussed previously, Whittal described the use of an exponentially decaying pulsed-ion extraction field to compensate for total energy disparities between low- and high-\( m/z \) ions. This system demonstrated improved mass accuracy when compared to square-wave TLF.\(^{63}\)

Kovtoun introduced the concept of mass-correlated delayed extraction, where a time-varied correction field is added to a static PIE field so that every iso-mass group has its own history of energy correction while traveling through the acceleration region of an ion source.\(^{93}\) This approach was applied to a MALDI/TOF device that demonstrated enhanced resolution for the simultaneous measurement of peptides in the range 900–4500 Da.\(^{94}\)

Dynamic pulse focusing techniques are demonstrating significant promise to improve the ease of use of linear TLF devices, because the need to adjust TLF parameters as a function of \( m/z \) ultimately may be eliminated. These dynamic approaches impart an \( m/z \)-dependent final velocity and total kinetic energy profile. Consequently, system calibration must be performed using a higher order calibration expression that accounts for the change in total kinetic energy as a function of ion TOF. Indeed, this may be the preferred method of parallel ion extraction for future linear TOF platforms.

### 6.4 The Ion Mirror or Reflectron

In 1973, Mamyrin introduced the concept of the ion mirror or reflectron.\(^{95}\) This device compensates for differences in \( U_o \) by making ions of different \( U_o \) travel proportionally different flight distances. Consider the ion-mirror-containing TOF system depicted in Figure 12. In this case, an ion source provides a space-focus object plane just outside of the ground aperture. At this point ions are spatially coherent but possess different final velocities because of varying initial \( U_o \). All ions continue in free flight until they enter the uniform-retarding electrical fields of the mirror. In the reflectron, ion velocity slows and reaches zero at the point where the product of ion mirror potential and ion charge is equivalent to total ion energy. Ions are then turned about and accelerated out of the mirror to reach an exiting velocity that is the opposite of the entrance velocity.

In this case, an ion with additional velocity \( \delta \) penetrates more deeply the reflectron field and travels a longer distance to the detection plane. This difference in total flight distance compensates for \( \delta \) and isomass ions arrive at the detection plane in temporal coherence. Tang et al. provide a more thorough mathematical derivation of this system.\(^{10}\)

Figure 13 depicts the two most common ion mirror geometries. The upper panel displays a coaxial reflectron system. In this arrangement, two detectors are employed: a linear or neutral detector and a reflected-ion annular detector. Ions are emitted from the source through the opening of the annular detector. For linear mode operation, the reflectron is maintained at free flight potential and all ions strike the neutral/linear detector. When the reflectron is energized, reflected ions are directed toward the annular detector. The off-axis...
geometry is shown in the lower panel. In this approach the same design may be employed for both detectors.

Over the years, reflectrons have been used in TOF analysis for ions formed from LDI (96–98) MPI (99) SIMS (100,101) MALDI (102) and ESI (54). Although performing relatively well in focusing ions below 10 000 Da, most reflectrons do not improve resolution for heavier ions. This is primarily due to two factors: background gas collisions within the reflectron, and metastable decay of larger ions. As ion m/z increases, so does ion cross-sectional area, as well as the probability of collision with background gas. When large ions are decelerated to near-zero velocities in the reflectron, collisions with background gas can create deleterious changes in ion position and velocity, manifesting as significant time spread at the detector.

Unimolecular decay of parent ions has been well established for a number of ionization schemes. (10,77,103) This decay results from bond scission that is a direct consequence of depositing excessive vibrational energy during ion desorption, desolvation, ionization, or extraction processes. The result is unimolecular or metastable decay, producing neutrals and product ions. During free flight, parent ions, product ions, and neutrals all have the same velocity. But because product ions and neutrals weigh less than parent ions, their total energy is less than that of their parent species. In this manner, the electrical field strength of the reflectron will not optimally focus all ions, and peaks exhibit significant fronting and asymmetry due to noncoherent early arrival of metastable products. This effect may be mitigated by the use of parabolic or curved-field reflectrons. (104,105) This concept will be discussed when considering tandem mass spectrometry (MS/MS) geometries, in section 14.

6.5 Higher Order Correction

As noted previously, TLF has demonstrated significant potential to improve the mass resolving power and accuracy for linear TOF devices by compensating for initial ion spatial, initial ion velocity, or initial ion formation time spread. First-order simultaneous correction of all three factors is not possible. In some TOF applications, such as MALDI, ions are ejected from a well-defined surface so the initial ion spatial spread is small. However, MALDI ions demonstrate significant initial velocity spread that is often exacerbated by collisions if ions are instantly accelerated by the application of a strong extraction field. (62) Although an ion mirror can provide first-order energy focusing, it cannot correct for time spread created during ion acceleration. (55) Consequently, the demonstrated resolution for systems combining MALDI, CIE and a reflectron is often less than that of a well-designed linear TLF device.

In the case of many continuous-flow interfaces, ions are formed with simultaneous initial velocity and spatial distributions. In this fashion, the simple application of either TLF or a reflection will not provide significant resolution enhancement. The desire to correct for both initial spatial and energy spreads has prompted many investigators to consider higher order correction approaches.

In 1974, Stein noted the possibility of both space and velocity focusing. Stein notes: “If a conservative force field is space focusing to a given order with particles starting at initial points and arriving at a final point, this same force field becomes velocity focusing to the same order by starting particles at the final point, reflecting them at the initial points and collecting them at the point from which they started”. Stein provided several theoretical models that demonstrated spatial and velocity focusing through the use of equal-momentum acceleration, time-varying fields, two-dimensional ion motion, and a combination of conditions such as Wiley–McLaren TLF with the ion mirror of Mamyrin. (106)

In 1989, Cotter suggested a similar “double-focusing” system consisting of TLF and a reflectron. In addition to higher order correction, it was felt that the employment of delayed ion extraction would uncouple parent ion fragmentation from ion acceleration, thus providing structural information and eliminating the metastable ion-defocusing effects often seen in reflectron systems. (23)

Vestal et al. demonstrated significant resolution improvements in parallel-extraction MALDI by combining TLF with a reflectron. During the analysis of adrenocorticotrophic hormone clip 18–39 (monoisotopic m/z 2465.2), Vestal demonstrated a twofold improvement of resolution for the TLF/reflectron system when compared to a linear TLF configuration. The same system used to analyze bovine insulin (average m/z = 5733.5) successfully resolved the protein’s isotopic envelope with a resultant resolution of 12,500. In this arrangement, TLF was used to create a first-order time focus near the initial point of free flight. Higher order energy focusing was provided by the reflectron. (74) In addition to reflectron focusing, the use of TLF in this double-focusing system also narrowed the initial ion velocity spread, because the collisions involved with immediate ion extraction were avoided. All of today’s research-grade parallel-extraction MALDI/TOF devices utilize this double-focusing geometry.

TLF and reflectrons are combined in all modern orthogonal extraction devices. In this arrangement, TLF is used to create a spatial focus plane just outside of the accelerating ion optics (see Figure 14). Energy focusing is accomplished using an ion mirror. Detection and space-focus planes are arranged to be equidistant from the reflectron. In this manner, reflected ions arrive at the detection plane with both energy
and spatial coherence. A similar device was used by Kurtchinsky to provide a deconvoluted mass spectrum of bovine insulin with isotopic resolution \( R = 10000 \).\(^{55}\) This geometry was later adapted to MALDI-generated ions.\(^{58}\) Unlike the parallel-extraction double-focusing geometries suggested by Cotter and Vestal, the double-focusing orthogonal MALDI system does not require the adjustment of TLF parameters as a function of ion \( m/z \). The latter is attributable to Wiley–McLaren space-focusing conditions that are independent of ion \( m/z \). In this fashion, orthogonal MALDI ion acceleration represents an easier-to-use solution when compared to parallel devices.

7 ANALYTICAL SENSITIVITY

The metric of analytical sensitivity is often described in terms of some detection limit established at a minimal S/N. Mass spectral data are typically displayed as a two-dimensional plot of intensity vs \( m/z \), where signal intensity is represented as total ion counts or some other arbitrary scale created to be proportional to total ion current for a given \( m/z \) domain. In either case, signal amplitude is taken to be the vertical displacement of the displayed peak as measured from the baseline.

Noise is often characterized in terms of its origin and frequency. In TOFMS, noise sources include electronic noise and chemical noise. For the most part, electronic noise such as thermal noise, environmental noise, shot noise, Johnson noise, and flicker noise, have been greatly reduced in today’s TOF instruments. Undoubtedly, the greatest contribution to overall TOFMS noise is chemical noise. Chemical noise is created by the arrival of time-incoherent particles to the detector surface. These particles are energetic ions, neutrals, and, in the case of negative ion scans, electrons that arise from events of ion creation, collection, and acceleration. Processes such as metastable decay, fast ion and electron bombardment of ion optic elements, and poor ion focusing promote chemical noise creation.

Noise manifests as random signals of various frequencies. High-frequency noise is most troublesome, because many times its frequency closely matches that of the measured signals and, as such, adds constructively and destructively to the overall signal profile. Intermediate and low-frequency noise generally create annoying baseline displacement and drift, often complicating automated peak height measurements. Noise has typically been quantified in terms of maximum peak-to-peak (p–p) amplitude or root mean square (RMS) values for a given TOF period. A S/N is calculated by dividing the

---

**Figure 14** An orthogonal electrospray TOF device equipped with quadrupole ion guide providing collisional cooling (q0). Two other quadrupole regions are included for MS/MS purposes (Q1 and q2). TLF performed in the ion optic assembly corrects for initial spatial distribution, whereas the ion mirror corrects for velocity disparities. (Figure courtesy of Werner Ens and Kenneth G. Standing, University of Manitoba, Winnipeg, Manitoba, Canada.)
total signal by the determined noise. Because signals are measured in terms of peak to baseline excursion, most investigators use the maximum p–p value near the time of signal detection for determining S/N. Overall S/N can be improved by summing a number of scans for a given measurement. Because true noise is random, summing \( n \) number of scans for a constant signal source improves the S/N by a factor of \( n^{1/2} \).

Detection limits are established in terms of total sample mass or sample concentration. The mass detection limit of a system is generally defined as the minimum quantity of analyte that can be detected with a given S/N, whereas the concentration detection limit is taken to be the minimum concentration of sample that can be detected under the same circumstances. Most laboratories established these detection limits at S/N = 2–3. As will be explained later, overall analytical sensitivity is affected by a number of factors, including analyte \( m/z \). However, generally, modern TOF devices demonstrate mass detection limits of the order of high attomole to low femtomole amounts of sample and concentration detection limits in the nanomolar scale.

7.1 Factors Affecting Analytical Sensitivity

Overall analytical sensitivity in TOFMS is a confounded product of sample ionization efficiency, ion collection efficiency, ion transmission efficiency, and ion detection efficiency. Sample ionization efficiency is dependent upon the ionization potential of the analyte as well as the efficiency of the ionization source. In some cases, ion suppression results from preferential ionization of other compounds within the sample matrix. These competing compounds could be other analytes present within a heterogeneous mixture or the necessary components of the sample matrix, such as buffers, ion-pairing agents, denaturants, chaotropic agents, or chromatographic mobile phases. Ionization source efficiency results from the combined effects of analyte desorption/desolvation and ionization. In terms of MALDI, this process is greatly driven by the geometry of the probed area, the applied laser fluence, and matrix efficiency. With respect to ESI, desolvation and ionization efficiency remain tightly coupled and are ultimately affected by flow rate. Improvements in this process have been made through source miniaturization and will be discussed later.\(^{\text{(107)}}\)

After formation, ions need to be collected and accelerated into the free flight region. During this phase, ion collection efficiency becomes dependent upon source duty cycle and focusing parameters. Duty cycle has been discussed previously and will not be elaborated further here. Ion focusing should proceed in a manner that ultimately corrals all ions of a given \( m/z \) to a point of temporal coherence upon the detection plane. In some cases, it is necessary to trade off resolution for sensitivity, because ions with extreme radial position or velocities may only be collected at the expense of total TOF spread.

Ion transmission efficiency is dependent upon perturbations of free flight as well as overall radial focusing. If analyzer pressure is too high, frequent collisions with background gas ultimately create radial and axial ion displacement, causing some ions to miss the detector and temporal incoherence among detector incident ions. For a given pressure and free flight distance, the probability of background gas collision is dependent upon ion cross-sectional area. In this manner, ion transmission efficiency for a given charge would be inversely proportional to \( \text{MW}^2 \). Likewise, the presence of multiple charges often produces coulombic forces of repulsion within a given ion, causing molecular unfolding or extension that increases cross-sectional area. This is of particular concern for ESI/TOF measurements of large proteins.

Many ions formed have some inherent radial velocity that must be controlled to ensure detector incidence. This is generally accomplished through the use of radial focusing in the ion optics to create an appropriately sized ion image upon the detector surface. Another approach incorporates an ion particle guide to diminish free flight radial spread. An electrostatic ion guide used for this purpose is described by a number of groups.\(^{\text{(37,71,81,108,109)}}\)

Ion detection efficiency is inherently linked to the probability of converting incident ions to electrons as well as the ability to provide subsequent electron gain. A number of factors come into play here, including fundamental properties of the detector and signal amplifiers. These are discussed in the next section.

7.2 Detectors for Time-of-flight Mass Spectrometry

Detectors for TOFMS are generally classified as electron multipliers or direct-measurement/charge-based detectors. Among the electron multiplier group, two distinctions are made: discrete dynode electron multipliers and continuous electron multipliers. Discrete dynode multipliers consist of a series of separate shaped plates or assemblies of plates connected together by a chain of resistors, usually of equal value (see Figure 15). In this manner, high voltage applied across the chain will create an equal voltage drop across each dynode. Potentials are established to drive secondary electrons down to the detector anode. This may be accomplished by raising the first dynode to some negative potential while maintaining the anode at virtual ground, or by grounding the first dynode and floating the anode to some positive potential. The latter is a preferred approach to circumvent the deleterious effects of accelerating metastable ion products.

An ion striking the first dynode will produce secondary electrons that are accelerated to the second dynode,
TIME-OF-FLIGHT MASS SPECTROMETRY

Figure 15 A discrete dynode electron multiplier detector. See text for details. (Figure courtesy of ETP Electron Multipliers, Ermington, Australia.)

and so on through the multiplier. Changing the applied voltage, usually over the range 1000–5000 V, varies the multiplier gain. Generally about 15–30 stages are used, with an interstage voltage drop of no more than 200 V. Interstage potential drops in excess of 200 V are likely to create field emission, thus elevating detector noise. Overall gain is usually of the order of about 10^8.

Continuous dynode electron multipliers consist of a single dynode surface. For TOFMS applications, microchannel plate (MCP) devices are most commonly used (see Figure 16). An MCP assembly is a lead silicate glass wafer with electrode etching containing a number of small channels. When suitably processed, these surfaces have secondary electron emission properties and are electrically resistive. About 60% of the MCP surface is comprised of these channels, and the remaining 40% provides structural integrity. A potential difference of about 800–1000 V is created across the MCP. Input ions strike the interior walls of a microchannel and release secondary electrons. An accelerating electrical field drives secondary electrons into the wall to create subsequent amplification. Output electrons are collected on the surface of the detector anode. Polarity considerations are similar to that of the electron multiplier, and varying the potential difference across the plate controls the gain. Maximum gain for this system is of the order of 10^4. Subsequent gain is achieved by stacking two or three of these MCPs in a chevron array. In this manner, the maximum gain ranges from 10^6 to 10^12.

As a general rule, MCP detectors have faster response times and broader analog bandwidths than discrete electron multipliers. However, compared to discrete electron multipliers, MCP multipliers have limited dynamic range. This is particularly true when a large ion load enters the first MCP of a stack, resulting in a saturating level of secondary electrons entering the second MCP. In this case, saturation is the direct result of charge depletion and acceleration field collapse. This effect creates a dead time period for which the second MCP remains refractory to electron gain and transmission. Because of the latter, many MCP-equipped TOF devices employ a means to minimize detector exposure to unwanted high ion currents. Ion deflection has been achieved through the use of electrostatic deflection lenses similar to that depicted in Figure 2. Furthermore, pulsed application of a perturbing voltage to electrostatic ion guides has also demonstrated utility in deflecting unwanted ions. Alternatively, pulsed application of a perturbing voltage to electrostatic ion guides has also demonstrated utility in deflecting unwanted ions. Another means of minimizing detector saturation is achieved by decreasing the gain so that secondary electrons are not subsequently amplified.

An extended dynamic range performance from MCP detectors has been achieved by linking the output of an MCP to a high-speed scintillator. In this manner, secondary electrons strike the scintillator surface to cause the emission of photons. Photon detection and subsequent gain are provided by a fast response photomultiplier tube. This arrangement avoids saturation, because there is no second MCP. Additionally, no anode is used, providing a facile means to float the output stage of the MCP without risk of deleterious anode discharge. This is particularly useful when applying post-acceleration fields for both positive and negative ions. A commercial embodiment of this device is available from Burle Electro-Optics Inc., (formerly Galileo Corporation), Lancaster, Pennsylvania, USA.

7.3 Electron Work Function, Post-acceleration, and Secondary Ion Generation

The first step of ion detection for all electron multiplier devices is ion to secondary electron conversion. Electron emission from conversion dynode surfaces is dependent upon the work function of that surface. Most dynode and MCP surfaces are coated with a low-work-function alloy or metal oxide so that a minimal amount of energy transfer can result in the emission of secondary electrons. Geno and Macfarlane described the probability of MCP
secondary electron emission as a function of the secondary electron coefficient, a term analogous to the electron work function. The probability of secondary electron emission was defined as shown in Equation (32), where \( P \) is probability and \( \gamma \) is the secondary electron coefficient as described by Equation (33), where \( m \) is ion mass and \( v \) is ion final velocity:

\[
P = 1 - e^{-\gamma} \quad (32)
\]

\[
\gamma = 2.58 \times 10^{-7}m[\exp(2.32 \times 10^{-4}v)] \quad (33)
\]

For \( \gamma = 5 \), about 99% of all incident ions create secondary electron emissions. Geno and Macfarlane noted that, for a given velocity, \( \gamma \) increases with increasing MW, and for a given MW, \( \gamma \) increases with increasing velocity. Consequently, for a given amount of ion energy, the probability of secondary electron conversion and overall detection sensitivity is inversely proportional to ion MW. This relationship predicts that about 100% ion detection sensitivity is achieved for human insulin (5807.65 Da) at about 35 keV energy, whereas more than 65 keV of energy is needed for near-optimal conversion of bovine IgG (MW \( \sim 150 \) kDa).

The acceleration of ions to energies greater than 30 keV is difficult if one relies solely upon ion optic acceleration. Problems with electrical stability often become limiting here. Additional ion energy is often provided by the use of a post-acceleration region just prior to the detector’s conversion surface. In this fashion, an additional 10–20 keV of energy may be supplied. For cations, a negative voltage post-acceleration field is employed, whereas a positive voltage post-acceleration field is used for anion detection. One shortcoming of this approach is the subsequent creation of time spread among free-flight metastable ion products.

The overall effect of post-acceleration upon the 3:1 S/N mass detection limit for MALDI ions of various MWs is demonstrated in Figure 17. Here all ions were accelerated to 25 keV and then subsequently post-accelerated with up to an additional 12.7 keV. As can be seen, modest improvements of the mass detection limit for human insulin and bovine \( \beta \)-lactoglobulin A is demonstrated, but appreciable detection sensitivity enhancement is shown for BSA and bovine IgG. These results are consistent with the theory of Geno and Macfarlane.

The use of a secondary ion generator (SIG) has shown utility in improving the detection sensitivity for large ions. Such elements are generally solid surfaces or moderate transmission grids that provide a means to generate secondary ions as a direct consequence of primary ion impact. The dynamics involved in this process have been studied by a number of researchers. In terms of direct ion generation, it is generally believed that the impact of primary ions upon SIG surfaces results in the sputtering of surface contaminant ions such asalkali metals, \( \text{H}^+ \), \( \text{H}^- \), and other adsorbed vacuum-system contaminants. Furthermore, secondary electron emission from these same contaminants occurs in the presence of a negative potential. I have discovered that a negatively biased copper mesh provides improved generation of secondary ions when compared to ground potential copper grids.

Because the MW of secondary ions is significantly less than that of the incident ions, subsequent post-acceleration of secondary products typically impart velocities that are greater than that of the original projectiles. In this fashion, the secondary ion conversion efficiency is greater than that for parent ions. In fact, even though the relative abundance of these secondary products is less than that of the parent ion, in many cases the amplitude of the measured secondary ion signal exceeds that of the high-molecular-weight parent ions. Figure 18 depicts a plot of the SIG signal normalized to the parent ion signal for a copper-mesh SIG/MCP detector system. As analyte MW increases, the ratio of the SIG-to-parent signal increases.

The disparate final velocities of post-accelerated secondary and primary ions complicate the use of the SIG signal to enhance the detection of high-molecular-weight ions. In many cases, subsequent post-acceleration of both populations results in attendant time spread and possible resolution of two discrete ion signals. I have demonstrated that these ion populations can be made temporally coherent to the detector by the use of a differential acceleration grid (DAG) positioned between...
Figure 18 SIG signal as a function of analyte MW. The relative ratio of parent ion signal normalized to parent ion signal is plotted against parent ion MW for a number of proteins ranging from 5800 to 97 000 Da. The normalized SIG signal increases with increasing projectile MW. Signals were generated during MALDI analysis using 25-kV acceleration potential, 10-kV post-acceleration potential, 60% transmission copper grid SIG, and MCP detection surface. (Unpublished data from Scot R. Weinberger.)

Figure 19 The effect of DAG potential upon BSA secondary and parent ion detector arrival times. See text for details. (Unpublished data from Scot R. Weinberger.)

the SIG and the detector surface. The DAG potential is controlled so that secondary ions are first softly accelerated, allowing primary ions to pass them. Upon moving through the DAG, secondary ions are accelerated to catch up with parent ions at the detector surface. Figure 19 demonstrates the effect of DAG potential upon secondary and parent ion profiles for MALDI-generated BSA cations. At zero DAG potential, secondary ions arrive at the detector before parent ions, and two discrete ion signals are noted. When the DAG is set to 1200 V, secondary ion arrival to the detector is slowed to be coincident with parent ion arrival. A single signal with improved resolution and S/N is achieved. Over-focusing is possible by setting the DAG to potentials greater than 1200 V. In this case, BSA parent ions precede the arrival of secondary ions. I have combined the above-noted SIG scheme with a 15-kV post-acceleration MCP detector assembly that has provided the ability to detect 700 amol of IgG (MW ~ 148 kDa) as well as the trimer [(3M + H)+, MW ~ 444 kDa] and tetramer [(4M + H)+, MW ~ 592 kDa] ions for 5 fmol of IgG (see Figure 20).

7.4 Direct Measurement/Charge-based Detectors

Because of the above-described molecular-weight-dependent loss of analytical sensitivity demonstrated by electron multipliers, many laboratories have been investigating the use of charged-based detectors to aid in the analysis of very large ions. Bahr described a Faraday cup type of detector creating a 2:1 S/N for the detection of 18 000 elementary charges. The overall efficiency of this device was better than most electron multipliers for ions greater than 30 kDa. Park and Callahan described an inductive detector that only used about 30% of all incident ions. The remaining 70% of the ion load are available for subsequent experiments. The overall resolution demonstrated by this device probably makes it impractical for most TOF applications. Benner et al. described an inductive tube detector with a detection limit of about 150 elementary charges. This ultrasensitive device has been applied successfully to the measurement of megabase DNA. To date, no commercial devices employ charge-based detector systems.

8 LIQUID INTERFACES FOR TIME-OF-FLIGHT MASS SPECTROMETERS

This section covers liquid interfaces coupled to TOFMS instruments, specifically ESI and the liquid separation methods coupled to it, including HPLC, CE, and CEC, as well as MALDI coupled with on-line liquid separation methods. ESI, being a solution-phase analysis method, is more readily coupled with liquid-phase separation techniques, hence the larger volume of literature on the topic. MALDI is more typically done using solid-phase matrices, such as 2,5-dihydroxybenzoic acid; coupling a liquid-phase separation to MALDI is thus inherently more difficult.

8.1 Electrospray Ionization

The challenge presented in performing ESI on a TOF instrument is in coupling a continuous ionization source to a mass spectrometer that is inherently pulsed. The TOF instrument requires precise measurement of the time between the start pulse and arrival of an ion packet at the detector; thus, ions cannot be introduced continuously into the analyzer region of the mass spectrometer but can only be introduced at specific intervals. The first widely known reported coupling of ESI to a TOF instrument was in 1992 by Boyle and Whitehouse. They overcame the problem of continuous ion introduction by developing a TOF instrument where the ions are introduced to the spectrometer between the ion repeller and extractor lenses in a direction that is orthogonal to the field-free flight region (see Figure 21). The ions are then pulsed into the field-free flight region to allow for their velocity-dependent separation and focusing by a two-stage reflectron. Simultaneously, the region between the repeller and extractor lenses, usually referred to as the ion storage region, is again allowed to fill ready for the next repeller/extractor pulse, giving a maximum duty cycle of approximately 25%. This instrument had a mass resolution of 1000 m/ddm.

Meanwhile, the independent development of orthogonal TOF with an ESI source had taken place at the Russian Academy of Sciences by Dodonov et al. in 1987. This instrument was also equipped with a two-stage reflectron and had a mass resolution of 1000 m/ddm.

A recent review of orthogonal injection of ions into a TOF instrument was completed by Chernushevich et al. in July 1999. They review the advantages of the orthogonal TOF configuration for continuous ion sources. Briefly, the TOF instrument can tolerate a relatively large spread in the velocity or spatial distribution of ions in the plane perpendicular to the spectrometer axis (y-axis) and typically there is a small velocity spread along the spectrometer axis (z-axis) such that high resolution can be achieved more readily.

An alternative method of coupling ESI to a TOF instrument was reported in 1993 by Lubman et al. Briefly, instead of injecting ions orthogonally the authors injected ions into a QIT for temporary storage of the ions before analysis by the TOF instrument. Since the first reports of coupling ESI to a TOF instrument, there have been several reports following the same basic configuration. Dodonov et al. had improved their instrument by 1994 such that it had a mass resolution limited only by their data collection system to 2000 m/ddm. That same year Dodonov and Laiko gave a theoretical treatment of the orthogonal TOF instrument equipped with a two-stage reflectron, complete with equations describing the expected resolution, spectral line shape, the effect of grid wires, and the effect of initial ion velocity. Also that year, Verentchikov et al. reported the development of an ESI/TOF instrument based on the Russian design that had a mass resolution of 5000 m/ddm for peptides. However, the resolution decreased with mass for all of the early orthogonal TOF instruments.

A dramatic improvement in the performance of ESI orthogonal TOF instruments came with the addition of collisional cooling or focusing developed by Douglas and French for quadrupole mass spectrometers. Collisional focusing is achieved through the use of an RF quadrupole or hexapole lens at elevated pressure, where collisions with surrounding gas reduce ion energies close to thermal values. Without collisional focusing, ions introduced from atmospheric pressure into a vacuum are essentially a supersonic beam where all ions travel at approximately the same velocity. As the ions are pulsed out of the ion storage region, they continue to travel orthogonally (y-component of velocity) with the same velocity as they had when entering the high-vacuum region. To strike the detector, the correct ratio of velocities of ions traveling along the flight path

![Orthogonal TOF device with hexapole ion storage](image-url)
interface (100–2000 an atmospheric pressure chemical ionization (APCI) of mass.

the required energy to strike the detector, independent reduces ion velocity to near-thermal values, after which they are electrostatically re-accelerated to give them the needed energy to strike the detector, independent of mass.\(^{(4)}\)

For the analysis of proteins, the vacuum pressure inside the high-vacuum region of the orthogonal TOF instrument is an important experimental parameter. Chernushевич et al. reported in 1996 that resolution of protein mass spectra is dependent upon the number of collisions between the protein ions and the residual background gas in the mass spectrometer, higher pressures giving more poorly resolved spectra.\(^{(128)}\)

Recently, commercial versions of the orthogonal TOF instrument equipped with an ESI interface have become available. The current manufacturers include PE Biosystems (Framingham, MA), makers of the Mariner Biospectrometry Workstation with a maximum pulse repetition rate of 11 kHz, Micromass Inc. (Manchester, UK), makers of the LCT with a maximum pulse repetition rate of 20 kHz, Analytica of Branford Inc. (Branford, CT), makers of the Enterprise API-TOF/MS (the instrument in Figure 21) with a maximum pulse repetition rate of 20 kHz, and Bruker Daltonics (Bremen, Germany), makers of the Bio TOF. The Mariner can be purchased with a standard ESI interface or the PE ScieX (Concord, Canada) ESI interface (for higher throughput applications) or the Nano-link Spray Chamber (nanospray) for high sensitivity/limited sample applications. The Micro-mass ESI TOF can be purchased with a standard Z-spray ESI interface or an interface with up to four ESI sprayers, known as the MUX Technology interface. Potentially, four HPLC systems can be connected to one orthogonal TOF instrument or alternatively two nozzles may be used for internal standard introduction for exact mass measurements. The Enterprise API-TOF/MS can be purchased with a standard ESI interface (1–1000 \(\mu\)L min\(^{-1}\)), an atmospheric pressure chemical ionization (APCI) interface (100–2000 \(\mu\)L min\(^{-1}\)), a low-flow ESI interface (50–1000 nL min\(^{-1}\)) or a dual ESI source. This source allows one to perform continuous internal calibrations for exact mass measurements without mixing for both HPLC or flow-injection analysis. The Bio TOF is intended for the study of noncovalent biological complexes and protein conformations. The nanoelectrospray source, developed by Wilm and Mann,\(^{(107)}\) has been incorporated onto the orthogonal quadrupole TOF instrument for peptide sequencing.\(^{(129)}\) Commercial versions of the quadrupole TOF instrument are available from Micromass (Manchester, UK), makers of the Q-TOF; and from PE-Sciex (Concord, Canada), makers of the Q-STAR.

8.2 Noncovalent Biological Complexes

The unlimited mass range of the TOF instrument makes it well suited for the study of large noncovalent complexes that would be beyond the mass range of most instruments. In 1994, Tang et al. reported the study of protein–protein noncovalent complexes on their recently constructed ESI orthogonal TOF instrument.\(^{(130)}\) On the same instrument, Fitzgerald et al. have shown large noncovalent complexes with \(m/z\) beyond 4000.\(^{(131)}\) Samples were introduced in 5 mM ammonium bicarbonate buffer at pH 7.5. The \(m/z\) distribution of the ions shifted to higher \(m/z\) ratios (lower charge states) at physiological pH and the protein hexamer was only observed with gentle declustering potentials (the potential difference between the atmospheric pressure plate and the first skimmer in the instrument); as the declustering potential was increased, the hexamer dissociated into pentamers, tetramers, and monomers. More recently, the same instrument was used to study protein–protein and protein–ligand equilibria.\(^{(132,133)}\) Equilibrium was observed between the \(Escherichia coli\) citrate synthase dimer and hexamer that depends upon the concentration of nicotinamide adenine dinucleotide (reduced form) (NADH). Hexamer complexes with a mass of 287,322 U were observed at \(m/z\) up to 10,000. A protein–ligand–DNA complex was also studied on the same instrument for the tryptophan repressor.\(^{(134)}\)

8.3 High-performance Liquid Chromatography/ Electrospray Ionization/Time-of-flight Mass Spectrometry

With the addition of the ESI continuous ion source to the TOF instrument, it was a natural transition to couple liquid separation methods to the TOF instrument through the ESI interface. As discussed previously, manufacturers offer ESI/TOF instruments capable of performing HPLC separations with or without HPLC control. A number of research groups have published reports combining HPLC separations with an orthogonal ESI/TOF instrument. Banks and Gulcickev developed an HPLC analysis method based upon separation on nonporous silica.\(^{(135)}\) They achieved a complete separation of the peptides from a myoglobin tryptic digest in 3.5 min. Chromatographic peak widths were of the order of 0.5–3 s, necessitating data collection at a rate of 16 spectra per second. Here the TOF instrument is especially advantageous because a complete spectrum is acquired with each pulse. Of course, the pulse rate is actually much
higher than 16 Hz so each spectrum was actually a sum of 512 spectra. Banks also showed the gain in sensitivity achieved by using smaller internal diameter LC columns.\(^{136}\) A 0.1-mm internal diameter column was 428 times more sensitive than a 2.1 mm internal diameter column packed with the same material. Nielen and Buijtenhuijs have used an orthogonal ESI/TOF instrument coupled to size-exclusion chromatography, gradient polymer elution chromatography, and LC at the critical point of adsorption for polymer analysis.\(^{137}\) They point to the higher duty cycle and extended mass range of the orthogonal TOF over the quadrupole MS instrument as critical to the analysis of larger oligomers and the detection of minor impurities.

The excellent mass accuracy of the orthogonal TOF spectrometer makes it possible to achieve continuous exact mass measurements from LC-separated compounds. Hogenboom et al. showed that with the post-column addition of a single internal standard, the exact mass of several LC-separated pesticides could be determined.\(^{138}\) With the use of a pesticide database, unambiguous identification of the pesticides was achieved in most cases, the only exceptions being isomeric compounds.

The quadrupole orthogonal TOFMS was recently investigated for its quantitative aspects as a high-performance liquid chromatography/tandem mass spectrometry (HPLC/MS/MS) instrument.\(^{139}\) They found it to have an impressive dynamic range of over four orders of magnitude, with better sensitivity than an on-line fluorescence detector for the compound 3,4-ethylenedioxyamphetamine.

### 8.4 Capillary Electrophoresis/Capillary Electrochromatography Electrospray Ionization/Time-of-flight Mass Spectrometry

The orthogonal TOF instrument is especially suited to liquid separation techniques that produce narrow chromatographic peaks (one to a few seconds in width). The TOF instrument is capable of collecting an entire mass spectrum with each pulse and modern data systems are capable of collecting several spectra per second, making the TOF more compatible with CE separations than the more widely used quadrupole mass spectrometer. CE interfaces for ESI/TOFMS was reviewed in 1997 by Banks.\(^{140}\) Several approaches can be used to interface CE to the ESI/TOF instrument. In 1994, Fang et al. reported a direct coupling of CE to a commercial ESI interface without the use of a sheath flow design. However, this must be weighed against the decrease in CE separation efficiency that would otherwise result if the CE buffer were compromised.

Muddiman et al. have developed a mathematical correction method for separating analyte signal from background noise when reconstructing the electropherogram in capillary electrophoresis/electrospray ionization/time-of-flight mass spectrometry (CE/ESI/TOFMS).\(^ {141}\) Their method, known as sequential paired covariance, can provide better than a 100-fold increase in the S/N of the electropherogram over simple integration of the total ion current. They used a sheathless interface design and maintenance of the ESI counter-electrodes and ESI interface at negative potentials of 3–4 kV. A typical problem with CE coupled to ESI is the limited choice in CE running buffer. This is especially problematic with the sheathless CE interface design, because the CE running buffer must be compatible with ESI. Feng et al. used 50 mM acetic acid in 50:50 methanol–water.\(^ {126}\)

It is more typical for capillary electrophoresis/electrospray ionization (CE/ESI) interfaces to use a sheath flow. In this configuration, the CE capillary is inserted through the ESI nebulizer assembly that delivers a liquid sheath flow (in addition to the gas sheath flow to assist in desolvation) that mixes with the CE column effluent. The sheath liquid is designed to allow efficient ESI so that CE buffers that are less compatible with ESI can be used. The sheath flow liquid is typically introduced at a few microliters per minute, whereas the CE effluent is typically introduced at a rate ten times less than the sheath liquid. Dilution of the CE effluent and thus the possible decrease in the sensitivity are natural consequences of the sheath flow design. However, this must be weighed against the decrease in CE separation efficiency that would otherwise result if the CE buffer were compromised.

![Figure 22](image.jpg)

**Figure 22** Comparison of the total ion currents from a peptide separation (amine-coated column) using TOF and quadrupole instruments. (Reprinted with permission.)
demonstrated the CE separation and detection of peptide standards.

Banks and Dresch have shown that CE-separated peptides and proteins that produce peaks 1–2 s in width are easily analyzed by an orthogonal TOF instrument, whereas peak detection suffered on their quadrupole mass spectrometer (see Figure 22). Eight spectra per second were collected (each a sum of 1024 spectra) on the TOF instrument compared to a maximum of one spectrum every 2 s on the quadrupole. They used a sheath flow design and were able to analyze leucine enkephalin with a limit of detection of 8 fmol. Lazar et al. developed a CE/ESI interface for an orthogonal TOF instrument. They used a sheath flow at higher flow rates and a sheathless design for flow rates less than 300 nL min⁻¹ (microspray), maintaining ~75% separation efficiency when compared to ultraviolet detection. In 1998, Lazar et al. reported an improved version of this interface with a limit of detection of 1–10 fmol for CE/ESI/TOFMS.

Cao and Moini have used CE/ESI interfaced to an orthogonal TOF instrument for the analysis of proteins followed by the analysis of the resulting tryptic peptides from these proteins for protein identification through database searching. McComb et al. developed a CE/ESI interface using a gold-coated capillary for the separation of proteins and peptides. Peak widths were typically 3–5 s for peptides with an S/N of 250–400 at femtomole sensitivity. Barrbridge et al. developed chromium–gold-coated capillaries for use in a sheathless CE/ESI interface that had a lifetime of approximately 100 h. Stable spray was observed from 30 nL to 1 µL min⁻¹ with a limit of detection of 68 amol for MRF (methionine-arginine-phenylalanine)-enkephalin using the instrument and data system developed by Lazar et al.

CEC combines CE with packed-column LC. Fast separations and narrow peak widths are typical with this technique. Choudhary et al. demonstrated the CEC separation of phenylthiohydantoin-amino acids using an orthogonal TOF instrument for detection through a sheath-flow ESI source. They used a gradient elution of a packed capillary column and a CE instrument to apply high voltage along the length of the column. The separation of twelve phenylthiohydantoin-amino acids was completed in 10 min, with all components resolved in a 75 µm × 15 cm column.

### 8.5 Matrix-assisted Laser Desorption-ionization

Unlike the ESI sources, there is currently no commercially available source for coupling a liquid separation method directly to a MALDI/TOF instrument. A recent review of this area has been completed by Murray in 1997. Off-line coupling of a liquid separation to MALDI does not require any special modification of the MALDI instrument and will not be discussed here. Two major on-line coupling methods are found in the literature. One method developed by Li et al. known as continuous-flow MALDI is similar to continuous-flow fast atom bombardment. The other method developed by Murray et al., known as aerosol MALDI, is an extension of aerosol interfaces previously developed for CE.

In continuous-flow MALDI a liquid matrix, 3-nitrobenzyl alcohol, is mixed with methanol, ethylene glycol, and the analyte (in 0.1% trifluoroacetic acid) and introduced to the mass spectrometer through a 75-µm fused-silica capillary. The capillary was buttted against a stainless-steel frit that was wrapped with filter paper to adsorb excess matrix and solvent. Desorption took place directly from the surface of the frit using an ultraviolet laser (Nd:YAG, 266 nm). This design was later changed to a fritless probe and coupled with an on-line HPLC separation. Here the matrix was added post-column through a mixing tee and introduced through the flow probe to the mass spectrometer. In both reports, the MALDI probe was introduced to the spectrometer orthogonal to the instrument axis. The mass spectral resolution was unimpressive, typically being of the order of 10–20 m/dm. A later report from Whittal et al. explored the use of a flow probe introduced directly through the center of the repeller plate of the MALDI instrument. In addition, the use of TLF or delayed extraction was also explored for improvement of the resolution. With TLF the resolution was improved to 2000 m/dm for peptides compared to ~200 m/dm using continuous extraction.

Aerosol MALDI is performed by directly spraying a matrix (4-nitroaniline)/analyte solution into the source region of a TOFMS. The aerosol particles are dried by passing the aerosol through a heated tube and then the dried particles are irradiated with an ultraviolet laser (Nd:YAG, 355 nm). Using a linear TOF instrument the aerosol MALDI apparatus has a mass resolution of ~6 m/dm for bovine insulin. For combination with LC separation, the matrix solution was added post-column via a mixing tee and the mixed solution was introduced through the aerosol MALDI interface. Improved mass resolution, to ~300 m/dm for peptides was demonstrated by Fei et al. for aerosol MALDI using a reflectron instrument and 2,5-dihydroxybenzoic acid as matrix. Fei and Murray also demonstrated the coupling of aerosol MALDI to gel permeation chromatography for the separation and characterization of polyethylene glycol and polypropylene glycol.

The on-line MALDI methods are far from routine and cannot compete with on-line CE or HPLC/ESI/TOFMS in terms of sensitivity, resolution, and ease of use at the
present time. Off-line separation combined with MALDI is a routine method of interfacing liquid separations to MALDI because no special interface is necessary.

9 TIME-OF-FLIGHT ANALYZERS WITH GAS-PHASE ION SOURCES

Compared to other forms of MS, the primary advantages of combining TOF detection with gas-phase analysis involve high-speed mass scanning, accurate mass assignment, and extended mass range. High-speed full-scan data acquisition facilitates analysis of transient processes and in particular opens up the possibilities for fast chromatography/MS. The possibility of accurate mass determination compared to quadrupole and QIT instruments extends the analytical power of empirical MW determinations. In the case of gas-phase sample introduction into the ion source, the higher mass range afforded by the TOF instrument is of no great benefit because the mass range is ultimately limited by sample volatility.

TOF with gas-phase ion sources has found broad application in molecular physics and chemistry due to its unique suitability for transient analysis. For example, a large amount of work has been done on laser ionization of gas-phase samples (the latter may be produced by laser ablation, laser desorption, arc, etc.).\(^{(46,90)}\) photoemission EI,\(^{(163)}\) CI (e.g. by metastable atoms),\(^{(164)}\) and even gas-phase cationization of peptides.\(^{(165)}\) Although this research allowed significant advance in these important fields, so far it has not resulted in a widely used analytical technique for gas-phase analysis.

From the other side, such a technique was born when TOF had been coupled to GC.\(^{(166)}\) Since then the main area of analytical activity has become GC/TOFMS. Therefore, this section will concentrate mainly on various aspects of GC/TOFMS. Owing to the vast amount of library spectral information and method development that has been done using EI, GC/TOFMS is also primarily based around the use of EI ion sources. As both an illustration of an application where the TOF instrument is used to analyze transient processes and an illustration of a relatively new gas-phase ion source, bacteria identification using pyrolysis and MAB will also be discussed.\(^{(164,167)}\)

9.1 Interfacing Continuous Ion Sources with the Time-of-flight Analyzer

9.1.1 Duty Cycle and Direct Current Ion Storage

The TOF analyzer has a high duty cycle when coupled to pulsed ion sources, because the source is not pulsed again until the ions from the preceding pulse have all arrived at the detector. Sample is therefore not wasted during the analysis period. To obtain high duty cycles with continuous ion beam sources some form of storage of the ions from the continuous ion beam is required during the analysis period. The most common approaches are:

- quasi-static ion storage (e.g. in the potential well of space charge)\(^{(3,95,168–171)}\)
- ion storage in RF fields\(^{(172,173)}\)
- orthogonal acceleration\(^{(174–178)}\)

Wollnik et al.\(^{(168)}\) have reused a method of creating the ions within a trapping electric field, which stores them prior to pulsing into the TOF mass analyzer\(^{(3,95)}\). This source has also been used in work by Enke et al.,\(^{(169,170)}\) and is used in the Pegasus™ GC/TOFMS instrument (Leco Instruments, MI, USA).\(^{(171)}\)

In a static-storage ion source, ions are created in an electrostatic potential well. For example, the potential well for positive ions can be created by two plates held at the same potential with an intermediate grid of a lower potential, or the attractive potential of the electron beam itself can also perform the function of the grid. Ions formed in the region between the two plates will have thermal energy and a potential energy determined by the potential at the position at which they were formed. Because the ions are formed in the potential well they will be trapped, and will oscillate to some extent between the two trapping plates. The trapping plate nearest the analyzer has a grid to allow transmission of ions out of the source once the voltages are pulsed to empty the source into the mass analyzer.

The TOF aberrations caused by the spatial spread of ions between the trapping plates can be corrected by a suitable arrangement of electric field slopes in the way described by Wiley and McLaren.\(^{(3)}\) During an analysis cycle the stored ions are ejected from the source by pulsing the voltages on one or both of the trapping plates to form acceleration fields of the required slopes for ion TOF space focusing.

A disadvantage of this form of ion storage is that the oscillations of the ions between the trapping plates mean that there is also a velocity distribution as well as a spatial distribution of ions. This leads to further time aberrations, which reduce the mass resolution of the instrument. In particular, there is a significant effect of “turn-around time” where ions travelling away from the analyzer at the time of ejection from the ion source have to stop and accelerate back towards the analyzer.\(^{(3)}\) Also, in GC/TOFMS applications ion loss rate from the potential well is adversely affected by the presence of carrier gas.\(^{(179)}\) Another important disadvantage of this source is grid contamination within the source.
9.1.2 Radiofrequency-storage Electron Ionization Sources

Sample utilization efficiency could be improved also by using a QIT\textsuperscript{173} or a simpler cylindrical ion trap as the storage device\textsuperscript{179}. In principle, this configuration also affords MS/MS experiments for molecular structure elucidation. Compromised mass resolution of the TOF analyzer, increased complexity of electronics, and low space-charge capacity of RF traps have impeded wide use of this type of source so far.

9.1.3 Orthogonal Acceleration Time-of-flight Analyzers

The most common method of coupling TOF with a continuous beam ion source is orthogonal acceleration. The use of orthogonal acceleration in TOF mass analyzers has meant that TOF can be coupled with any type of continuous ion source and still maintain a reasonably high duty cycle\textsuperscript{174–178}. The use of orthogonal extraction helps to reduce the effects of “turn-around time” and initial velocity distribution in general, thereby improving the mass resolution of the instrument.

In orthogonal acceleration the continuous beam from the ion source is collimated and enters a field-free region between two plates at low energy (usually several tens of volts). Collimation of the beam reduces the component of energy orthogonal to the input direction of the beam. Ions are injected into the mass analyzer by pulsed voltages on one or both of the plates defining the field-free region to produce an acceleration field. As with the storage source, the magnitudes of the acceleration fields are chosen to provide TOF space focusing of the beam width. The direction of extraction and timing is orthogonal to the direction of input of the ion beam, i.e. in the direction where the energy spread has been minimized via collimation of the input ion beam.

The ion packets injected into the mass analyzer are accelerated usually to several kilovolts. Orthogonal acceleration provides ion storage by virtue of slow filling of the extraction region due to low input energy and relatively fast analysis time after acceleration to several kilovolts. The duty cycle depends on the relative lengths of fill time to analysis time. Analysis time is dependent on the mass range to be analyzed and on the size of the instrument.

9.1.4 Orthogonal Extraction Time-of-flight Analyzer with Electron Ionization Source

The EI sources used in conjunction with orthogonal acceleration TOF analyzers tend to be similar to EI sources used on quadrupole or magnetic sector instruments. The EI source is usually located in a differentially pumped region adjacent to the orthogonal acceleration module.

Output from the GC column is normally directly inside the ionization volume of the EI source. Aside from the speed of analysis, TOF analyzers yield EI spectra identical to those found in the standard libraries. The TOF system could therefore use already existing protocols of gas chromatography/mass spectrometry (GC/MS) analysis.

Commercially available orthogonal acceleration GC/TOFMS instruments with conventional EI sources are the SprinT\textsuperscript{180,181} (Figure 23) (HD Technologies Ltd., Manchester, UK) and the GCT\textsuperscript{180,182} (Micromass, Manchester, UK). The GCT\textsuperscript{180,182} also offers CI sources and field ionization sources\textsuperscript{182}.

9.1.5 Orthogonal Extraction Time-of-flight Analyzer with Supersonic Molecular Beam

A completely different type of GC/MS interface is the SMB interface\textsuperscript{183,184}. Davis et al. have coupled an SMB interface with an orthogonal extraction TOF analyzer for GC/MS analyses (Figure 24).\textsuperscript{185} In the SMB interface the GC column eluent is mixed with a make-up gas at atmospheric pressure and the mixture is expanded through a 150\textmu m heated nozzle into a low-pressure region. The make-up gas is helium or hydrogen. The sample molecules from the GC eluent are entrained in the supersonic expansion and the supersonic beam is skimmed at different stages of differential pumping prior to passing into the ionization region.

The interface consists of several differentially pumped stages to reduce the pressure from the atmosphere to the high vacuum in the TOF analyzer. The GC column eluent and make-up gas expand into a region pumped by a 28-m\textsuperscript{3} h\textsuperscript{-1} rotary pump that reduces the pressure to around 0.8 Torr. The SMB is skimmed into a second stage that is pumped by a 70-L s\textsuperscript{-1} turbo pump, which reduces the pressure to around 5 mTorr and further skimmed into...
Figure 24 Layout of the HyperJet MS system, which illustrates the HyperJet sources and their orientation to the TOF extraction region and analyzer. Pressure in the “T” connecting the column is close to atmosphere. See text for further details. (Figure courtesy of HD Technologies, Manchester, UK.)

Another feature of SMB/EI is the ability to perform background ion filtration. The total energy of the ions after acceleration, from a conventional EI source, is determined by the voltage in the ion source volume where the ions were formed. In the case of SMB/EI there is an additional component of energy due to the kinetic energy that the molecules possessed in the SMB at the time of ionization. Background molecules that were not entrained within the SMB will have only thermal kinetic energy at the time of ionization. This means that background ions can be filtered out using a simple energy filter and therefore any source memory effects are minimized.

Amirav et al. have also developed a surface ionization source for the SMB interface known as hyperthermal surface ionization (HSI), which has also been used for GC/MS. Most HSI work has been done so far in the positive ion mode. The positive-ion HSI source involves collision of the SMB with a heated rhenium foil. The active surface is rhenium oxide, which is maintained by oxygen at a pressure around 10 µTorr in the vicinity of the foil. The hyperthermal energy of the molecules in the SMB allows the molecules to overcome the image

Figure 24 Layout of the HyperJet MS system, which illustrates the HyperJet sources and their orientation to the TOF extraction region and analyzer. Pressure in the “T” connecting the column is close to atmosphere. See text for further details. (Figure courtesy of HD Technologies, Manchester, UK.)

a region containing the ion source that is pumped by another 70-L s⁻¹ turbo pump. The pressure in the ion source region is around 100 µTorr. The ion beam from the ion source passes through a conductivity restrictor into the TOF analyzer, which is pumped by a third turbo pump to a pressure in the low microtorr range. The turbo pumps all have a drag stage to maintain a sufficient compression ratio for pumping the light gases and so they can be backed by the same rotary pump from the first stage.

In the supersonic molecular beam/electron ionization (SMB/EI) source the supersonic beam of neutrals flows through the middle of a region where they are bombarded with ionizing electrons. The multitude of collisions in the supersonic expansion results in vibrational cooling of the molecules and the molecules have much lower internal energy prior to ionization compared with a more conventional EI source. The lower internal energy results in less fragmentation and molecular ion enhancement. The degree of molecular ion enhancement is compound dependent but is particularly evident in compounds like long-chain hydrocarbons where the molecular ion is the base peak in the mass spectrum.

Another feature of SMB/EI is the ability to perform background ion filtration. The total energy of the ions after acceleration, from a conventional EI source, is determined by the voltage in the ion source volume where the ions were formed. In the case of SMB/EI there is an additional component of energy due to the kinetic energy that the molecules possessed in the SMB at the time of ionization. Background molecules that were not entrained within the SMB will have only thermal kinetic energy at the time of ionization. This means that background ions can be filtered out using a simple energy filter and therefore any source memory effects are minimized.

Amirav et al. have also developed a surface ionization source for the SMB interface known as hyperthermal surface ionization (HSI), which has also been used for GC/MS. Most HSI work has been done so far in the positive ion mode. The positive-ion HSI source involves collision of the SMB with a heated rhenium foil. The active surface is rhenium oxide, which is maintained by oxygen at a pressure around 10 µTorr in the vicinity of the foil. The hyperthermal energy of the molecules in the SMB allows the molecules to overcome the image
potential close to the surface. Ionization efficiency is a function of the difference between the ionization potential of the molecule and the work function of the surface. Rhenium oxide is an efficient surface for the formation of positive ions because it has a high work function. The ionization efficiency is dependent on the ionization potential of the molecules. Molecules with low ionization potentials will be ionized more efficiently. This leads to selectivity of the HSI source on the basis of ionization potential. For example, in the case of crude oil analysis, the aromatic components are ionized very efficiently but there is very little ionization of the aliphatic components.

The sensitivity of the HSI source can be very high. For compounds with low ionization potentials, such as anthracene and lidocaine, the ionization efficiency can be up to two orders of magnitude higher than EI. HSI mass spectra often show fragment ions, but the mass spectral fingerprints are generally different to those from EI.

9.1.6 Orthogonal Extraction Time-of-flight Analyzer with a Metastable Atom Bombardment Ion Source

In the MAB source, ionization is effected by a beam of excited neutral atoms. The excited atoms are generally noble gases, although molecular gases such as nitrogen can also be used. The beam of neutrals is created using a Penning discharge and charge exchange, somewhat akin to the fast atom bombardment gun. The ion source is very similar to an EI source where the electron beam is replaced by the metastable atom beam.

The interesting thing about the MAB source is that the energy available for ionization and fragmentation is discrete, i.e. fixed to the excitation energy of the atom. This means that the MAB source has selective ionization and fragmentation capabilities through the use of different rare gases in the atom gun. If helium is used, there is substantial fragmentation similar to an EI mass spectrum. If xenon is used, the ionization is very soft and the spectra consist basically of molecular ions.

The combination of MAB with TOF has been used for bacteria identification using pyrolysis, and has several advantages for this application. The complex spectra normally obtained using pyrolysis with EI are much simplified when the MAB source is used to produce molecular ions and eliminate the fragmentation from the complex mixture. The fast data acquisition of the TOF analyzer also allows the transient process to be characterized. The time profile of the spectra emerging during the pyrolysis process provide a characteristic fingerprint of the bacteria.

9.2 Aspects of Gas Chromatography/Time-of-flight Mass Spectrometry

9.2.1 Trade-offs of Analysis

Mass spectrometer designs are subject to various constraints to give the best compromise in operating parameters for their intended application. TOF instruments are no exception and compromises must be made in relation to parameters such as mass resolution, mass accuracy, sensitivity, and accuracy of quantitation. These parameters also have an impact on coupling with fast chromatography.

The trade-off between mass resolution and sensitivity is perhaps most familiar to those involved in MS. In general, higher mass resolution results in less sensitivity. In the case of orthogonal acceleration TOF instruments, higher mass resolution instruments require longer flight paths. Longer flight paths mean that the analysis time increases relative to the fill time of the push-out region and therefore the duty cycle (and hence sensitivity) of the instrument is reduced. Mass accuracy and quantitation are also intimately linked to these parameters.

For a given number of ions in a mass spectral peak, the higher the mass resolution, the better will be the mass accuracy of the determined peak centroid. With higher mass resolution the time width of the peak is narrower and therefore the time error for the centroid position will be smaller. However, the accuracy of the centroid of the peak is also a function of the ion statistics within the peak, i.e. the mass accuracy of the peak is limited by the number of ions in the peak. The number of ions in the peak is related to sensitivity, which is related to mass resolution. In other words, mass accuracy is not just a function of mass resolution. It is possible to get the same mass accuracy from a lower resolution instrument; this is subject of course to their being sufficient mass resolution to resolve isotopic peaks in the lower resolution case and the lower mass resolution instrument having sufficient transmission and duty cycle to provide correspondingly higher ion statistics. This also means that even high-resolution instruments will not be able to provide accurate mass at trace levels of signal.

If we now impose the additional constraint of chromatographic timescales there are yet more trade-offs that must be examined. In GC/MS a fixed amount of sample is injected and the compounds elute in a short time frame. Orthogonal TOF instruments have a very high underlying DAR, typically tens of kilohertz. At an acquisition rate of 40 kHz there are 40 000 individual mass spectra obtained per second. However, there are generally not enough ions in one of these mass spectra to be statistically meaningful, and in any case this is far too much data to store to disk at this rate. As a result, a number of individual shots
are added together before the resultant mass spectrum is saved to disk. For GC/MS mass ranges, mass spectra can be saved to disk at rates of up to several hundred per second. At an acquisition rate of 40 kHz, if 100 spectra per second are saved to disk then each mass spectrum will be the sum of 400 individual shots. For a given chromatographic peak the number of ions in the mass spectral peaks will thus be a function of the scan rate, where scan rate in this context refers to the number of spectra per second saved to disk.

This means that there is a compromise between scan rate and mass accuracy, because the ion statistics are poorer at higher scan rates. Limits of detection will also be a function of scan rate because S/N will be poorer at high scan rates for the same statistical reasons. To maintain levels of mass accuracy and S/N at high scan rates, the ions available need to arrive in a narrower time window, i.e. the GC peaks need to be narrower.

9.2.2 Quantitation

For signals well above the detection limit, quantitation on a GC/TOFMS is relatively independent of the scan rate. This is due to the very fast underlying DAR of several tens of kilohertz. The number of ions at any given mass from a GC peak will be the sum of ions from the individual spectra obtained during the elution time of the peak. This total sum will remain the same if it is partitioned into several sub-sums during the time of peak elution, i.e. if a higher scan rate is used. The higher scan rate simply adds more points to the histogram representing the integral under the GC peak. However, at very high scan rates the accuracy of quantitation may be reduced due to difficulties in peak detection within the stored mass spectra because of poor ion statistics. A higher scan rate, however, provides more points across the GC peak, thereby better defining the chromatography. The greater the number of points across the peak, the easier it will be to deconvolve closely eluting peaks.

9.2.3 Dynamic Range

The dynamic range of TOF instruments is limited mainly by its data acquisition system. In ion counting mode using a TDC not more than 0.5 ion per shot per mass could be acquired, which limits the counting rate by $1 - 2 \times 10^4$ counts $s^{-1} \text{mass}^{-1}$. With background typically at levels of a few counts $s^{-1} \text{mass}^{-1}$, this limits the dynamic range by $10^3 - 10^4$. This dynamic range tends to exceed that of microbore columns. However, it is not sufficient for standard narrow-bore fused-silica columns. The required extension of dynamic range may be achieved by using an ADC running alongside the TDC.$^{(186–188)}$ Alternatively, a multi-anode detector and multiple TDCs may be run in parallel.$^{(189)}$

10 INDUCTIVELY COUPLED PLASMA/ TIME-OF-FLIGHT MASS SPECTROMETRY

It is probably true to say that the entry of TOF into the field of ICP MS has proved to be a formidable task due to the maturity of this field. Indeed, several TOF parameters were to be enhanced sometimes by orders of magnitude from typical values just to achieve performance of the already highly developed quadrupole and sector instruments.$^{(190)}$

The progress in ICP/TOFMS instrumentation development is summarized in Table 3. Generally, ICP/TOFMS has approached average levels typical for quadrupole mass spectrometers (except that sensitivity continues to be inferior at higher masses). Presently, two commercial ICP/TOFMS systems are available: the Optimass 8000$^{(191)}$ produced by GBC Scientific Pty. Ltd. (Australia),$^{(188,191)}$ and the Renaissance$^{(192–195)}$ produced by Leco Incorporated (St. Joseph, MI, USA). Both machines consist of a differentially pumped atmosphere-to-vacuum interface, focusing ion optics, pulsed ion accelerator, pulsed ion gate for removal of matrix ions, ion mirror, and a multidynode electron multiplier. In the Optimass 8000$^{(191)},$ ions after leaving the focusing ion optics are accelerated orthogonally to the original direction of their motion. In the Renaissance$^{(192)}$ ICP/TOFMS instrument ions are accelerated along the same direction.

The main driving force of ICP/TOFMS development is associated, as usual, with unique applications, possibly due to the speed and all-mass detection capabilities of the TOF analyzer.$^{(196)}$ For high-throughput multi-element analysis ($>5–10$ samples min$^{-1}$, with $>10–20$ elements monitored), ICP/TOFMS could provide better overall performance (sensitivity, isotope ratio accuracy, dynamic range) than sequential analysers. For laser-ablation atomization, ICP/TOFMS provides a unique capability of quasi-simultaneous (within $<0.1$ ms) multi-element monitoring. In terms of high-throughput multi-element monitoring, the success of ICP/TOFMS will depend on improvements of sample introduction techniques. GC,$^{(197)}$ LC, supercritical fluid chromatography, capillary zone electrophoresis, field-flow fractionation, counter-current chromatography, etc. have been interfaced to ICP/TOFMS with different degrees of success.$^{(198)}$ Development of these hyphenated techniques will strongly benefit from the parallel-analysis capability of the TOF analyzer. For laser ablation applications, the success of ICP/TOFMS will depend on improving the robustness of the atmosphere-to-vacuum interface in the presence of relatively high contamination caused by laser-sputtered samples.$^{(196)}$

11 QUADRUPOLE ION TRAP/ TIME-OF-FLIGHT MASS SPECTROMETRY

The QIT accumulates ions, thereby amplifying the observed ion current, especially for weak ion beams.\(^{203}\)

In addition, the QIT offers other advantages for mass analysis, including MS/MS.\(^{204}\) Typically, mass-selective detection is used for ions trapped in a QIT.\(^{205}\) However, an alternative approach involves a TOF mass analyzer for “simultaneous” detection of the ions, thereby enabling a much more rapid analysis.\(^{206}\) In addition, for ions produced using a continuous ionization source, such as ESI, the QIT provides a convenient interface for converting the continuous beam of ions into discrete packets for TOFMS. Thus, the duty cycle is essentially limited only by the trapping efficiency of the QIT. Consequently, a QIT/TOFMS enables ions to be detected over a wide \(m/z\) range without scanning, thereby offering a means for rapid analysis, suitable for applications such as a detector for a fast separation technique.

Although QIT/TOFMS was described as early as 1979,\(^{173}\) Lubman et al. were the first to explore the potential of this hybrid for analytical applications,\(^{206–208}\) including the first description of electrospray ionization/quadrupole ion trap/time-of-flight mass spectrometry (ESI/QIT/TOFMS).\(^{123}\) Figure 25 shows a (simplified) schematic of a QIT/TOFMS instrument used as a detector for an external ionization source. Ion optics (typically Einzel lenses) before and/or after the QIT are also used with this hybrid but have been omitted in this diagram for simplicity. The operation of the QIT/TOFMS instrument can be divided into two events: ion storage and ion extraction. During ion storage, both endcap electrodes...
are typically held at ground potential while an RF voltage (typically a frequency of ~1 mHz and an amplitude of 200–3000 \( V_{p-p} \) are used) is applied to the ring electrode. A buffer gas (e.g. helium) is also added to the QIT to assist in cooling ions to the center of the QIT. The buffer gas is especially important for reducing the kinetic energies of externally generated ions that pass into the QIT through one of the endcap electrodes. Under the appropriate conditions, ions will have stable trajectories within the QIT and will undergo collisional cooling and accumulate in the center of the QIT. After a predetermined trapping time, ions are extracted from the QIT, which now serves as part of the acceleration region of the TOFMS instrument. In the first ESI/QIT/TOFMS study, the RF voltage was shut off, and after a small time to allow for the decay of the RF voltage the ions were extracted from the QIT by pulsing the exit endcap electrode. The extracted ions separated in the drift tube of a reflectron TOFMS instrument and were detected using dual MCPs.

The role of several parameters, including the RF voltage and the method of ion extraction, on the performance of QIT/TOFMS has been investigated. Chambers et al. reported significant improvements in their QIT/TOFMS spectra by using a technique known as “RF clamping”. With this method, the RF voltage is turned off and immediately clamped to zero instead of being allowed to decay. A decaying RF voltage during ion extraction will cause broadening in the velocity distribution of the ions, thereby decreasing the observed mass resolution. Pulsing both endcap electrodes (bipolar extraction) instead of only the exit endcap electrode (unipolar extraction), to maintain a more uniform electric field in the extraction region, was also introduced. This change resulted in significant improvements in the mass resolution of the QIT/TOFMS spectra and is now used routinely. Finally, the role of the QIT in this hybrid has been expanded by Lubman et al., who have recently described procedures for MS/MS.

To date, the emphasis of the literature published on QIT/TOFMS has involved the use of this hybrid as a detector for fast separation techniques such as CE. However, QIT/TOFMS has been used also to investigate unimolecular reactions in the gas phase. Furthermore, although ESI has been most commonly used with QIT/TOFMS, the implementation of other ionization sources, both internal and external to the QIT, has been described.

Several studies have used ESI/QIT/TOFMS to investigate small analytes; however, the analysis of higher MW compounds, such as proteins, has not been nearly as successful. Purves and Li showed that in their linear QIT/TOFMS instrument the quality of mass spectra for protein ions in excess of ~20 000 Da degraded rapidly. The reason was attributed to the higher pressure (~10\(^{-3} \text{ to } 10^{-4} \text{ Torr}\)) in the acceleration region due to the buffer gas. This result is not surprising because Chernushevich et al. have shown that the mass spectra of protein ions begin to degrade at pressures as low as 10\(^{-8} \text{ Torr}\) in orthogonal ESI/TOF. Consequently, a conflict in the analysis of larger MW species with this hybrid arises because the buffer gas plays a crucial role in trapping externally generated ions. For this hybrid to be useful for the analysis of protein ions, this fundamental problem must be addressed. Other methods of ion cooling need to be explored or, alternatively, the ion trap could be uncoupled from the extraction process (a method for the latter is described below).

Several variations of the original design of the QIT/TOFMS instrument have been reported. For example, Wang et al. developed a QIT that was orthogonal to a TOFMS instrument to allow uncoupling of the operation of the QIT and TOFMS. In addition, some recent hybrids reported in the literature have significant changes compared with the Lubman design, but retain the common theme of trapping ions and subsequent analysis using TOFMS. Three of these designs that are still in their early development stages are described below.

A segmented-ring, cylindrical ion trap TOFMS instrument was reported by Enke et al. This design replaces the hyperbolic-shaped electrodes with planar endcaps, and two, thin, circular diaphragms further approximate the cylindrical ring electrode. This geometry produces a unidirectional linear field during ion extraction and thereby avoids the need to cool the ions to the center of the ion trap. The advantage of this technique is that a high mass spectral generation rate can be maintained (>1 kHz) compared with QIT/TOFMS (<100 Hz).

The linear ion trap (LIT) coupled to a TOFMS instrument was reported by Douglas et al. This instrument uses an RF-only quadrupole that is coupled orthogonally to a TOFMS instrument. By using timed stopping potentials on the entrance and exit apertures of the quadrupole, an ion trap is created. Although results to date with LIT/TOFMS are not comparable with QIT/TOFMS, LIT/TOFMS offers some advantages over QIT/TOFMS, such as a higher ion capacity. Furthermore, the separation of the trapping hardware from the acceleration region of the TOFMS instrument in LIT/TOFMS may offer additional advantages in the analysis of larger MW analytes.

Finally, an entirely different type of ion trap that is operational at atmospheric pressure (760 Torr) has been developed for use with a TOFMS instrument. This ion trap was developed based on the ion focusing principles of a cylindrical-geometry, high-field, asymmetric-waveform ion mobility spectrometer. The mechanism by which an ion is trapped is based on changes in ion mobility at
high fields and is dependent on ion properties other than \(m/z\). The use of this ion trap with TOFMS may offer advantages for analytical applications.

At the present time, there are no commercial versions of QIT/TOFMS devices.

12 MATRIX-ASSISTED LASER DESORPTION/IONIZATION TIME-OF-FLIGHT MASS SPECTROMETRY

Undoubtedly, the most widely applied laser desorption technique to date has been MALDI. Two groups independently developed MALDI: the group of Tanaka and the group of Hillenkamp.\(^{12-15}\) Further historical details of these developments are found in section 2 of this article. A number of reviews have been written regarding this technique.\(^{102,225-227}\) Consequently, this section will provide a brief overview of MALDI fundamentals and popular applications.

12.1 Matrix-assisted Laser Desorption/Ionization Fundamentals

MALDI is a desorption/ionization technique for poorly volatile compounds that utilizes the energy inherent in a moderately focused pulsed laser. Although the technique has been applied to liquid samples,\(^{152,154,157-162}\) it has been far more successful in the analysis of solid-state crystals or thin films. Consequently, this section will only focus on solid-state MALDI analysis.

MALDI samples are prepared on the surface of a solid probe (see Figure 26). Generally speaking, analytes are mixed with a solution containing a laser energy-absorbing compound, known as the matrix. Sample and matrix material can be premixed prior to probe deposition or mixed directly on the probe surface.\(^{228-230}\) In some instances, a seed layer of matrix is first applied followed by the addition of a sample–matrix mixture.\(^{231,232}\) Sample–matrix co-crystallization is allowed to proceed by atmosphere evaporation,\(^{12}\) or by rapid evaporation facilitated by the application of a vacuum.\(^{233}\) Although the exact nature of desorption and ionization are still being investigated, it is clear that the generation of quality ion signal depends upon efficient sample incorporation into the matrix material. In this fashion, it is necessary to match the solubility characteristics of the matrix to the analyte. Additionally, it is necessary to match the absorbance maxima of the matrix to the spectral wavelength of the laser source. Most commercial MALDI devices use inexpensive nitrogen lasers (\(\lambda = 337\) nm). Table 4 lists some of the commonly used nitrogen-laser-compatible matrices for bioanalysis, along with their application and solvent systems.

After crystallization, the probe is inserted into the TOFMS instrument where it becomes intimate with the repeller lens of the ion optic assembly. In some cases, such as with two-dimensional sample stages, the probe is the repeller. After a brief pump-down period, desorption and ionization are promoted by a short-duration pulse (typically <10 ns) of moderately focused laser light. Coarsely speaking, desorption and ionization are achieved by a thermal energy transfer process from the matrix to the analyte.

In contrast to LDI microprobe techniques that highly focus incident laser radiation to small spots (<10 \(\mu\)m in diameter) and high irradiance (10\(^{12}\) W cm\(^{-2}\)),\(^{233}\) MALDI typically employs spots of the order of several hundred microns in diameter with resultant power densities of about 10\(^6\) W cm\(^{-2}\).\(^{102}\) Ultraviolet lasers used in MALDI include: nitrogen lasers; excimer lasers; frequency-doubled,

Figure 27  Atmospheric pressure MALDI interface. An atmosphere housed MALDI source is coupled with an orthogonal acceleration TOF device (Mariner oa-TOF, PE Biosystems, Framingham, Massachusetts, USA). See text for further details. (Figure courtesy of Professor Alma L. Burlingame, University of California at San Francisco.)

Excimer, pumped-dye lasers ($\lambda = 220–300$ nm); and Q-switched, frequency-tripled and -quadrupled Nd:YAG lasers ($\lambda = 355$ and 266 nm, respectively).\(^{(102)}\) Infrared lasers used in MALDI applications include: transverse electrode atmospheric (TEA)–CO$_2$ ($\lambda = 10.6$ $\mu$m); Er:YAG ($\lambda = 2.94$ $\mu$m);\(^{(156,240,241)}\) and optical parametric oscillator lasers ($\lambda = 2.8–3.3$ $\mu$m).\(^{(242,243)}\)

Originally, MALDI sources were coupled with linear, constant, parallel ion extraction TOF devices.\(^{(12)}\) Eventually ion mirrors were added, improving the resolution for low-molecular-weight compounds.\(^{(13,102)}\) The rediscovery of TLF and its subsequent addition to MALDI analysis resulted in significant improvements in mass resolving power and mass accuracy.\(^{(63,70,74,77–83,93,94,244)}\)

Higher order corrections combining TLF with reflectrons has extended the mass resolving power of this approach to about 20 000 $m/dm$, with low parts-per-million mass assignment error.

For all of the above-mentioned TOF geometries, MALDI ions are generated in vacuo and parallel ion extraction is utilized. Recently, a number of groups have experimented with orthogonal acceleration extraction coupled with the generation of MALDI ions at elevated pressures.\(^{(4,58–61)}\) Initial attempts at orthogonal extraction of MALDI ions met with modest success. Difficulties with initial spatial and velocity distributions created spectra with poor resolution and sensitivity.\(^{(56,57)}\) The addition of collisional cooling within a quadrupole ion guide greatly improved matters.\(^{(58)}\) Eventually, a tandem orthogonal MALDI quadrupole–quadrupole TOF device was created, capable of high accuracy, high-resolution MS and MS/MS operation.\(^{(4)}\) This device is described further in section 14 of this article.

Laiko and Burlingame introduced the concept of atmospheric pressure MALDI when they combined an external MALDI source with an orthogonal TOF analyzer (see Figure 27). They reported a reduced level of unimolecular decay, possibly due to collisional dampening with atmospheric gas. Superior analysis for multicomponent peptide mixtures was demonstrated compared to conventional MALDI.

Verenchikov et al. combined the MALDI, two-dimensional sample stage of a commercial device (Voyager, PE Biosystems, Framingham, MA, USA) with the same orthogonal TOF analyzer used by Laiko and Burlingame (see Figure 28). This device was used to analyze a number of proteins as well as DNA molecules.\(^{(59)}\) Optimum ion stability was demonstrated when desorption was performed at 1 Torr of pressure. Detector post-acceleration technology was employed to enhance the sensitivity of the device for large proteins.\(^{(60)}\) Isotope-envelope-limited resolution for enolase, a protein of 47 kDa MW, was demonstrated. The authors also noted partial resolution of BSA isoforms. Because of the latter, they now believed protein resolution to be limited by sample heterogeneity.\(^{(59)}\)
Orthogonal acceleration MALDI geometries employing collisional cooling have a number of advantages when compared to in vacuo, parallel extraction approaches. These include:

- Uncoupling the initial ion position and time of creation from the TOF measurement obviates concerns for precise sample positional and electrical clamping.
- Ions are extracted at rates 1000-fold greater than they are created. This allows single ion per m/z detection and the use of low-cost TDC devices.
- Desorption performed at elevated pressures permits the use of higher laser energies without deleteriously effecting signal fidelity. This circumvents the need to hunt and peck for good crystals, greatly facilitating analysis.
- The combination of the two preceding points allows for the creation of a pseudo-continuous introduction of ions. In this manner, MALDI ion current stability approaches that of GC and LC sources.
- Higher order TLF and reflectron focusing provides enhanced resolution at all m/z values without the need to adjust pulse voltage or time lag parameters.
- Calibration of ion TOF is independent of initial conditions, making the calibration extremely linear over several orders of m/z magnitude.

Because of these factors, orthogonal MALDI systems show great promise in simplifying and enabling the use of this analytical technique.

12.2 Matrix-assisted Laser Desorption/Ionization Applications

MALDI has been extended to the analysis of small molecules, (245–249) organic polymers, (5,14,15,250–256) proteins, (12–15,75,102,111,225,230,234,235) oligosaccharides, (258–265) and oligonucleotides, (9,59,244,266–268) The preponderance of matrix chemical noise has greatly limited the utility of MALDI to study compounds with m/z < 1000. In terms of organic polymer analysis, difficulties in ionizing many species coupled with sample preparation and instrumentation effects upon the determination of mean MW and polydispersity have also limited the acceptance of MALDI in this analytical arena. (252,253) Consequently, this review will focus on the applications of protein/peptide, oligonucleotide, and oligosaccharide analyses.

12.2.1 Protein and Peptide Analysis

Proteins and peptides were the first compounds successfully studied by MALDI. (12–15,102,225,230,252,253,257) As such, it was a natural step to link MALDI analysis to LC and gel-isolated proteins. LC-isolated proteins and peptides are generally collected as fractions and, in off-line fashion, mixed with matrix for MALDI analysis. Although in situ MALDI analysis of gel-isolated proteins has been developed, (285) this direct approach has demonstrated poorer resolution and mass accuracy when compared to off-line approaches. Consequently, most laboratories link MALDI analysis to gel-isolated proteins through the use of membrane blots or buffer extraction. (286–290)

Although providing a facile means to assess rapidly the purity or to analyze mixtures, very little information is actually afforded by an accurate MW assignment for a given protein population. Significant analytical power is unleashed when MALDI/TOF analysis is combined with enzymatic and/or chemical modification of target proteins, enabling the elucidation of structural components, post-translational modifications, and protein identification. During this process, a sequential or parallel application of protein modifications is often employed, followed by MS analysis. MS profiles are reconciled with a priori knowledge of protein characteristics.

Peptide mapping of proteins has been facilitated by the use of various endopeptidases. (291,292) Subsequent peptide maps have been submitted for protein and cDNA database searches in attempts to provide possible protein identification. (293) Exopeptidases have been applied to peptides for the purpose of generating a ladder sequence. (294,295) In this fashion, enzyme/substrate ratio and digestion times are altered to create overlapping peptide populations with varying degrees of exopeptidase digestion. The resultant spectrum creates a ladder of

Figure 28 MALDI orthogonal acceleration TOF device (o-TOF) of Verentchikov et al. See text for details. (Figure courtesy of Dr Anatoli Verentchikov, PE Biosystems, Framingham, MA, USA.)
signals where primary amino acid sequence is revealed by taking the mass difference between adjacent peaks (see Figure 29). Chemical methods of creating peptide ladder sequences have also been developed. Protein post-translational modifications have been studied through the use of phosphorylases and deglycosidases.

12.2.2 Oligonucleotide Analysis

Early attempts at MALDI analysis of DNA and RNA using various protein matrices produced spectra of poor resolution and sensitivity. Compared to proteins and peptides, the analysis of oligonucleotides was complicated by a strong affinity for alkali metals and significant unimolecular decay. Ion exchange approaches utilizing cation-exchange beads or ammonium salts of organic acids functioned well to eliminate superfluous sodium or potassium ions, simplifying oligonucleotide ion profiles to primarily parent molecular ions.

The primary source for oligonucleotide unimolecular decay has been attributed to gas-phase acid-catalyzed base loss among purines and cytidine. Credence to this mechanism has been further provided by experiments in which 7-deaza-guanosine and 7-deaza-adenosine nucleosides demonstrated significant improvements in MALDI stability when compared to their normal analogs. Ultimately, the discovery of milder matrices such as 3-hydroxypicolinic acid, 2,4,6-trihydroxyacetophenone, and 2,6-di-hydroxyacetophenone facilitated MALDI analysis of oligonucleotides. The latter, coupled with TLF MALDI/TOF geometries, has greatly extended the mass resolving power and mass accuracy for MALDI oligonucleotide applications.

As was the case for protein analysis, accurate MW assignments of species within oligonucleotide mixtures only provide indications of purity or mixture status. Primary sequence information can be created when DNA or RNA molecules are enzymatically or chemically perturbed. Unlike proteins, the problem of sequence determination is facilitated by the fact that the smallest MW difference among all bases is about 9 Da (thymine and adenine). Primary sequence analysis of oligonucleotides has been performed using 3′- and 5′-exonucleases, as well as primer-based dideoxynucleotide chain termination approaches.

12.2.3 Oligosaccharide Applications

MALDI analysis of carbohydrates is complicated by the fact that these species have very low proton affinities. As such, ionization typically occurs by conjugation.
with an alkali metal, usually sodium or potassium.\(^{(262)}\) Often the analysis is aided by the addition of a small amount of alkali salt to preferentially drive the ionization process to a single species. Dilute sodium chloride or potassium chloride solutions (<1 mM) are typically used. For the most part, 2,5-dihydroxybenzoic acid has been used for this application.\(^{(262)}\) Mohr et al. found the addition of 1-hydroxy isquinoline to 2,5-dihydroxybenzoic acid improved resolution, S/N, and tolerance to buffer solutions.\(^{(261)}\) The use of 2,4,6-trihydroxyacetophenone or 6-aza-thiothymine, along with negative ion scanning, proved effective for the analysis of acidic oligosaccharides and glycopeptides.\(^{(263)}\)

Numerous papers report the analysis of complex oligosaccharides and glycoproteins by MALDI/TOF.\(^{(258–262,264,265)}\) As was the case for proteins, peptides, and oligonucleotides, oligosaccharide characterization has been performed using a combination of enzymolysis and MS. Exoglycosidases have been used to elucidate primary sequence and conjugation sites for n-linked glycoforms.\(^{(258,259)}\) PSD analysis has also been used to provide oligosaccharide structural information.\(^{(242,265)}\)

### 13 SURFACE-ENHANCED LASER DESORPTION/IONIZATION

The advent of ESI\(^{(48,301,302)}\) and MALDI\(^{(12,14)}\) has extended the application of TOFMS to the study of proteins within complex biological systems. However, the nascent state of biological materials such as blood, sera, plasma, lymph, interstitial fluid, urine, exudates, whole cells, cell lysates, as well as cellular secretion products, typically precludes direct TOFMS analysis. These samples are usually complex, heterogeneous mixtures of many biomolecules, often in the presence of excess organic and inorganic salts. As such, significant sample preparation and purification steps need to be employed prior to MS investigation.

Classical methods of sample purification, such as LC (ion exchange, size exclusion, affinity, and reverse phase), membrane dialysis, centrifugation, immunoprecipitation, and electrophoresis, are labor intensive, often demanding a preponderance of sample and suffering from attendant analyte loss due to nonspecific binding and dilution effects. In this fashion, a direct, facile means for TOFMS study of proteins capable of detecting major and minor components is not easily realized. Furthermore, the desire to characterize proteins by the combined use of chemical/enzymatic modification followed by MS analysis often requires considerable off-line sample manipulation. Clearly, a simple platform allowing for serial and parallel alterations of the same sample would greatly facilitate the efficiency of this approach.

The need for an improved, simplified technique that offloaded complicated protein extraction, purification, and characterization requirements became quickly evident. In 1993, the concept of SELDI was suggested by Hutchens and Yip.\(^{(303)}\) SELDI was described as a new strategy for MS analysis of macromolecules that provided an improved means for sample extraction and effective on-probe investigation of biopolymers when compared to conventional LDI or MALDI approaches. This landmark work incited enthusiastic interest in a number of researchers and sparked a cascade of studies in a plurality of laboratories.\(^{(268,273,286,288,304–319)}\)

Soon SELDI applications were described in terms of MS immunoassay,\(^{(312)}\) Probe-Immobilized Affinity Chromatography/MS,\(^{(320)}\) Probe Affinity MS,\(^{(307)}\) and Solid Phase Probe Extraction.\(^{(319,321,322)}\) Over the past 6 years, this technology has been applied successfully not only to the study of peptides and proteins,\(^{(242,268,274–268,288,303–307,309–316,320,323–333)}\) but also to the analysis of oligonucleotides,\(^{(266,267,271)}\) bacteria,\(^{(308)}\) and small molecules.\(^{(334)}\)

Recent advances in SELDI technology has led to the creation of a ProteinChip® Array System (Ciphergen Biosystems, Inc., Palo Alto, CA, USA) that has been applied successfully to a number of biological problems.\(^{(335–339)}\) The ProteinChip® Array system is a SELDI-based, protein analysis platform that incorporates a straightforward sample preparation and detection approach, which de-emphasizes the need for sample preparation and MS expertise.

#### 13.1 Surface-enhanced Laser Desorption/Ionization Versus Laser Desorption/Ionization and Matrix-assisted Laser Desorption/Ionization

Although distantly similar to LDI and MALDI, SELDI possesses a number of significant functional and practical distinctions from these other MS techniques. All three of these techniques rely upon the energy inherent in a focused laser beam to promote the creation of gaseous ions from mostly solid-state matter. Samples of interest are presented as crystals or thin films upon a sample support typically referred to as a probe. For both LDI and MALDI applications, the sample probe surface plays a passive role in the analytical scheme. The probe merely presents the sample to the mass spectrometer for analysis. In this fashion, raw samples must first be fractionated and desalted in order to produce a usable TOF signal. Furthermore, in the case of MALDI, large biopolymer analysis is only possible when analytes are co-crystallized with a solution of energy-absorbing compounds, typically referred to as matrix.
In contrast to LDI and MALDI, the sample probe used in SELDI plays an active role in the overall analytical scheme. As originally defined by Hutchens and Yip, SELDI consists of three subsets of technology: surface-enhanced affinity capture (SEAC), surface-enhanced neat desorption (SEND), and surface-enhanced photolabile attachment and release (SEPAR).\(^{303,333,340}\) In SEAC, the probe surface plays an active role in the extraction, presentation, structural modification, and/or amplification of the sample. This is accomplished by creating an affinity interaction between the probe surface and the analytes of interest. Figure 30 depicts a number of SELDI ProteinChip\textsuperscript{®} Array surfaces used in SEAC applications. Two fundamental surfaces are shown: chemical and biochemical surfaces. Chemical surface probes may be coated with reverse-phase, ion-exchange, immobilized metal affinity capture (IMAC) and mix-mode chromatographic media. In this case, analyte–stationary-phase dynamics proceed as predicted by the intermolecular attractive forces of hydrophobic, electrostatic, coordinate covalent bond, and Lewis acid–base interaction.

Biochemical surfaces contain covalently bound macromolecules such as antibodies, DNA, enzymes, receptors, ligands, and lectins. These surfaces facilitate the study of biomolecule–biomolecule interactions, as well as providing a means for specific sample extraction and enrichment, or on-chip enzymatic modification.

The process of SELDI sample fractionation for a number of chemical surfaces is demonstrated in Figure 31. A series of orthogonal SELDI surfaces are arranged in parallel array. Raw sample solutions are deposited upon each active spot. Each chip is washed with appropriate eluent in a gradient manner so that subsequent locations experience a greater degree of stringency, removing analytes with weak surface interaction potential and enriching those of strong surface affinity. When biochemical surfaces are employed, specific interactions are usually in play and a single surface is used with a gradient of wash conditions.

Independent of surface characteristics, SEAC functions as a solid-phase extraction technique that allows for sample clean-up and enrichment directly on the surface of the MS probe. This direct approach has a number of advantages when compared to MALDI or LDI. Because analyte is retained as dictated by surface affinity, retained compounds are driven to a state of physical–chemical homology. Under these conditions, the probability of analyte signal suppression is reduced when compared to MALDI analyses. Furthermore, in situ clean-up effectively diminishes sample loss by eradicating the effects of excessive dilution or nonspecific binding to sample purification vessels. Finally, because surface interaction potential is dependent upon physical–chemical properties such as hydrophathicity, total charge, \(pI\), phosphorylation, glycosylation, and primary composition, a priori knowledge of the analyte is provided when compounds are retained to a given surface under a specific set of wash conditions.

SEND is a process by which analytes may be desorbed and ionized without the need for the addition of matrix. This is accomplished by attachment of an energy-absorbing compound to the probe surface using the process of covalent modification or physisorption.\(^{340}\) Compared to SEAC, this technology is still in its germinal stages and, with the possible exception of small molecule analysis, has demonstrated limited utility. SEPAR is a hybrid combination of SEAC and SEND, where the affinity capture device also functions as an energy-absorbing molecule promoting analyte desorption and ionization. Like SEND, this technology is also in its infancy.

After purification upon the SELDI surface, analyte detection is achieved by the use of a TOFMS system equipped with a laser desorption ion source. In the case of SEAC analysis, a matrix solution is added to promote laser-based ionization and desorption. SEND and SEPAR surfaces are analyzed directly.
TIME-OF-FLIGHT MASS SPECTROMETRY

13.2 Surface-enhanced Laser Desorption/Ionization Applications

Because of the similarities between MALDI and SELDI, SELDI applications encompass all of the analytical possibilities for MALDI while providing improved performance in many areas. Unlike MALDI, the analysis of small molecules is facilitated by the use of SEND surfaces.\(^{340}\) Because no matrix is added, SEND analyses have a significantly diminished level of chemical noise in the low-molecular-weight domain, facilitating the detection of analytes with \(m/z < 1\) kDa. Recently, SEND-like applications on the surface of modified porous silicon have been demonstrated.\(^{334}\)

SEAC applications have been applied to the extraction of analyte from complex biological fluids. Figure 32 displays a multiplex antibody extraction of human prostate cancer antigen (PCA) and prostate-specific antigen (PSA) from serum. Unlike other immunoassay techniques, SEAC allows for simultaneous analysis of different antigens, because detection is based upon \(m/z\) assignment and not some bulk property such as radioactivity, fluorescence, or luminescence. A copper IMAC chip has been used to extract histidine-rich amino acids from fetal calf serum at concentrations approaching 50 fmol \(\mu L^{-1}\) (see Figure 33). As demonstrated here, the modified SEAC surface does not perturb mass accuracy. Resolution for this analysis was of the order of 2500 \(m/dm\).

A more general application of SEAC involves differential protein display for phenotypic investigation in the arenas of functional genomics and biomarker discovery. Biomarkers are biological compounds indicative of a particular physiological or pathological state. In many instances, these biomarkers are proteins or protein conjugates. During the initial discovery phase, protein profiles for control and experimental groups are compared in an attempt to elucidate statistically significant differences in protein expression. Various biological samples are analyzed using the previously described SELDI purification scheme, and the protein profiles detected for each group are contrasted. Reliable correlations between

![Figure 32](image1.png)

**Figure 32** SEAC antibody isolation of PCA and PSA from human serum. Human serum albumin (HSA) pseudomolecular ions of \((M + 3H)^{3+}\) and \((M + 4H)^{4+}\) are also detected. (Unpublished data courtesy of Ciphergen Biosystems, Palo Alto, CA, USA.)

![Figure 33](image2.png)

**Figure 33** IMAC for Cu extraction of angiotensin I and II, angiotensinogen, and dynorphin from fetal calf serum. Fetal calf serum was spiked with 50 fmol \(\mu L^{-1}\) of each peptide. See text for further details. (Unpublished data courtesy of Ciphergen Biosystems, Palo Alto, CA, USA.)
disease state or biological activity are made with upward or downward expression of a single or multiple protein signals. These proteins become biomarker candidates and the process of characterization begins.

Biomarker candidates are characterized by on-chip application of various chemical or enzymatic strategies to fragment the protein into constituent peptides in order to identify post-translational modifications, provide primary sequence information, and ultimately elucidate protein identity. As a typical starting point, proteins are reduced chemically and then exposed to endoprotease digestion. The resultant peptides may also be treated with dephosphorylating, deglycosylating, or exoprotease enzymes. At each step along the way, MS detection is performed to monitor changes in the peptide m/z profile. Observed m/z changes are reconciled with known enzymatic or chemical modes of action to provide structural insight. Peptide profiles of biomarker digests are used to mine protein and cDNA databases for possible matches.

converted to a virtual gel display for viewing simplicity. Near-homogeneous purification of the biomarker candidate is achieved by washing the surface of a mixed-mode chip with a buffer solution at pH 7.5. Figure 35 demonstrates the result of an on-chip tryptic digest of the enriched candidate. Peptide signals were used to mine protein and cDNA databases. Combining these results with data generated by collisional-induced dissociation MS/MS analyses allowed for unambiguous identification of the marker as seminal basic protein. Validation studies for confirming the utility of seminal basic protein as a prostate cancer biomarker are currently under way.

14 TANDEM TIME-OF-FLIGHT MASS SPECTROMETRY

TOF analyzers have been combined in tandem fashion with a plurality of analyzers, including magnetic sector, electrostatic analyzer, ion trap, quadrupole, and TOF devices. A thorough review of this subject is provided by Cotter.\(^3^{41}\) For the most part, TOF tandem arrangements have been created in order to provide structural information of biopolymers. Characterizations of post-translational modifications and primary sequence determination studies have been performed. A didactic review of MS amino acid sequencing of proteins is provided by Biemann and Payayannopoulos.\(^3^{42}\)

Protein characterization, as performed by MS/MS, primarily requires initial enzymatic or chemical cleavage into peptides. MS-based fragmentation of peptides then proceeds through unimolecular decay or collision-induced mechanisms. Regardless of mechanism, peptide fragments are classified in terms of parent ion cleavage location and product ion charge retention. Medzihradzsky and Burlingame provide a detailed discussion of this nomenclature along with postulated reaction mechanisms.\(^3^{43}\)

Figure 36 outlines the nomenclature involved in labeling peptide/protein MS-generated fragments. Two primary classes of ions exist: \(x,y,z\) and \(a,b,c\). If ion cleavage results in charge retention on the N-terminus, the ion is of the \(a,b,c\) class. If charge retention is located on the C-terminus, the ion is of the \(x,y,z\) variety. Cleavage between the carbonyl group and an N-terminal \(\alpha\)-carbon results in the creation of either \(x\) or \(a\) ions. Cleavage at the amide bond results in the creation of \(b\) or \(y\) ions, whereas cleavage between the amine and C-terminal \(\alpha\)-carbon creates \(z\) or \(c\) ions.

This section further examines tandem time-of-flight mass spectrometry (TOFMS/MS) analysis in terms of ISD, PSD, and collision-induced dissociation (CID).

14.1 In-source Decay

Although not a true form of MS/MS, ISD analysis does provide structural information for purified compounds. ISD is a prompt decay process for which parent ions fragment into products while remaining in the ion optic region. In this manner, product ions and intact parent ions are accelerated to the same final kinetic energy, allowing direct analysis and accurate MW determination for all species when using a simple, linear TOF device. ISD in TOF applications has been reported for PDMS,\(^3^{39}\) MPI,\(^3^{46}\) and MALDI.\(^3^{77,344-350}\) Currently, ISD is mostly used in conjunction with MALDI analysis, and, as such, subsequent discussion will focus upon this application.

Matrix-assisted laser desorption/ionization/in-source decay (MALDI/ISD) analysis is best performed using a TLF device. During the lag period, ions undergo prompt decay, and are subsequently accelerated out during the ion extraction phase. For the most part, \(c\) and \(y\) series ions are generated. As fragment MW increases, predominantly \(c\) ion fragments are seen.\(^3^{38,344}\)

The problem in performing ISD analysis is that there is no means to select the precursor or parent ion. Consequently, product ions form from all species, and if the sample is impure, interpretation becomes complicated. Even so, ISD has shown reasonable utility in the sequencing of a number of purified peptides,\(^3^{349}\) as well as identifying disulfide-linked peptides.\(^3^{347}\) In contrast to other forms of MS/MS, ISD does demonstrate reasonable efficiency in the direct analysis of large peptides and proteins.\(^3^{346,350}\) Figure 37 depicts a series of c-ion fragments generated during direct ISD analysis of BSA (MW = 66,430 Da).

14.2 Post-source Decay

Like ISD, PSD is a unimolecular decay process, but on a longer time frame. PSD occurs typically several
microseconds after ion creation. In this fashion, fragmentation takes place during free flight, after ions have been accelerated out of the source region. PSD has been reported for SIMS,\(^{10}\) MPI,\(^{43}\) and MALDI/TOF MS.\(^{103,104,265,348,351-366}\) Again, the focus of this section is on matrix-assisted laser desorption/ionization/post-source decay (MALDI/PSD) analysis.

MALDI/PSD analysis is typically performed using a reflectron-type TOFMS (see Figure 38). Precursor ion selection is accomplished using an electrostatic ion gate. Fragment ions enter the reflectron and get turned about according to their entrance energies. Because metastable decay occurs during free flight, product ions and neutrals have the same velocity as parent ions but less mass. Accordingly so, the total kinetic energy of these fragments can be considerably less than that of their parent ion. Although reflectrons function to compensate for variations in total kinetic energy, most linear field reflectors do not adequately focus ions over a broad energy range. Consequently, PSD analysis is generally performed by scanning the reflectron through a series of applied voltages. Because reflectron ion deceleration and acceleration are voltage dependent, a separate calibration function must be derived for each scan. Linking the results of each scan together in histogram fashion creates a composite MS/MS spectrum. This approach was first used by Schlag for MPI analysis,\(^{43}\) and was later applied to MALDI by Spengler.\(^{363,364}\)

Compared with linear field reflectors, the curved field reflector of Cotter has a broader energy focusing range and can be used without scanning (see Figure 38).\(^{105}\) This approach greatly simplifies PSD analysis, because a single spectrum provides an entire PSD/MS/MS profile. This device has been used for CID analysis,\(^{104}\) peptide sequencing,\(^{352}\) as well as generating fragment information on atomole levels of small peptides.\(^{366}\) Recently, this curved-field reflectron PSD has been combined with carboxypeptidase activity to create what has been termed as nested PSD spectra (see Figure 39).\(^{357}\) Intact peptides are simultaneously analyzed with carboxypeptidase products. In this manner, additional C-terminal fragments are created, improving the overall efficiency of fragment yield and sequence call.

PSD peptide fragments are generally of the \(a\), \(b\), and \(y\) variety. Additionally, side-chain fragments as well as fragments with the addition of water and losses of ammonia have been reported.\(^{351,360,362,363}\) For the most part, efficient PSD analysis requires at least 500 fmol of peptide. The overall complexity of interpreting these spectra combined with the relatively low efficiency of this process has limited its general applicability. For the most part, collision-induced dissociation/tandem mass spectrometry (CID/MS/MS) approaches provide easier to interpret results with significantly lower sample requirements.
**TIME-OF-FLIGHT MASS SPECTROMETRY**

14.3 **Collision-induced Dissociation/Tandem Mass Spectrometry Techniques**

Unlike ISD and PSD, CID is a bimolecular process where ions generally collide with collision gas molecules (see Figure 40). These collisions occur within a specialized region known as a collision cell. Collision cells have been bordered by electrostatic lenses,\(^\text{(353,356,367–369)}\) formed within ion trap bodies,\(^\text{(370,371)}\) and RF quadrupole arrangements.\(^\text{(4,55,58)}\) Low-energy CID occurs with collision energies typically less than 200 eV. High-energy collisions usually involve collision energies of 1000–10\,000 eV.\(^\text{(343)}\)

CID fragmentation produces products that conserve mass and charge. Singly charged parent ions fragment into a neutral and product ion, whereas doubly charged parents create a single doubly charged product ion and neutral or two product ions. For the most part, \(b\) and \(y\) ions are formed. This process is generally more efficient than unimolecular decay mechanisms, often providing more complete fragmentation profiles and sequence information, even at femtomole levels of peptide. Parent ion selection is performed in MS\(_1\) and product ion analysis is performed in MS\(_2\). Tandem TOF approaches generally employ a TOF device as MS\(_2\), taking full advantage of this system’s scan speed and mass range.

Three major tandem TOF geometries are currently showing promise for efficient CID/MS/MS operation: ion trap TOF, tandem TOF, and quadrupole–quadrupole TOF. Ion trap TOF has been applied to the analysis of ESI-,\(^\text{(208,215,216)}\) and MALDI-formed ions.\(^\text{(370,371)}\) For the most part, tandem TOF analyzers have been used for MALDI analysis.\(^\text{(353,356,367–369)}\) No commercial versions of ion trap TOF or tandem TOF devices exist today. Quadrupole–quadrupole TOF devices have been applied to ESI- and MALDI applications.\(^\text{(375,376)}\)

Commercial versions of ESI quadrupole–quadrupole TOF are presently available from Micromass (Manchester, UK) and PE-Sciex (Concord, Canada). An LDI quadrupole–quadrupole TOF device developed by Krutchinsky, Loboda, Spicer, Dworschak, Ens, and Standing has recently demonstrated significant MS/MS efficiency for the MALDI analysis of human angiotensin I (see Figure 41). The overall signal quality for the MS/MS analysis of 4 fmol of angiotensin I was found to be similar to that for 4 pmol.

**Figure 39** Nested PSD spectrum of human angiotensin I treated with carboxypeptidase \(y\). The upper spectrum reveals additional C-terminal peaks due to elimination of the C-terminal amino acid leucine. (Figure courtesy of Kratos Analytical, Manchester, UK.)

**Figure 40** CID collision cell schematic. See text for details.
15 TIME-OF-FLIGHT SECONDARY ION MASS SPECTROMETRY

When a beam of energetic primary ions is directed onto and impinges upon a solid surface, atoms and molecules of the surface are released. This process is known as sputtering and it defines the fundamentally destructive nature of this method of analysis. A small fraction of the atoms and molecules released from the surface carry a charge. These “Secondary Ions”, when mass analyzed, form the basis for the technique known as Secondary Ion Mass Spectrometry or SIMS for short.

The development of this technique has generated two separate application areas. In the first, use is made of the phenomenon known as sputtering. Here, the primary ion beam has two purposes: to erode the atomic surface in a controlled way and therefore investigate the atomic composition of the surface as a function of depth; and to maximize the efficiency of production of positively charged secondary ions by producing the primary ion beam from a chemically aggressive atomic species such as oxygen. Cesium primary ion beams similarly enhance the yield of negative secondary ions. This technique, which has become known as dynamic SIMS depth profiling, has established itself as the standard method for the determination of the concentration profile of semiconductor dopants.\(^{(377)}\) It can deliver accurate concentrations from the 1% level down to parts per billion over a range of depths down to the micron level. However, the property of the technique that gives rise to this extraordinary atomic sensitivity has a side-effect: the chemically active primary ions become incorporated into and thereby alter the chemical nature of the surface. Although this phenomenon may be tolerable to the semiconductor analyst, it can be a major disadvantage to the surface chemist. Surface analysis thus represents the second area of the applications of SIMS referred to above.

15.1 Concept of a Maximum Dose

Consider a monolayer of surface. Each square centimeter consists of approximately \(10^{15}\) molecules. In order that the technique is regarded as nondestructive to the surface as a whole, only about 1% of the surface molecules may be interrogated. This gives a maximum number of molecules available for analysis by SIMS of \(10^{15}\). If one incident primary ion removes a maximum of ten molecules then the maximum permitted primary ion dose is \(\sim 10^{12}\) primary ions for one square centimeter of surface. Suppose that one cares to examine the surface by taking account of the spatial distribution of chemistries to a minimum feature size of \(\sim 10\) \(\mu\)m. Now the maximum dose has reduced to only \(10^6\) primary ions. At a continuous primary ion current of 1 nA this represents a maximum experimental analysis time per pixel of 160 \(\mu\)s. Clearly any type of scanning mass spectrometer is going to find
the task of collecting the full mass range in this short time impossible should more than a single \( m/z \) be analyzed at any time. However, with a TOF mass spectrometer the situation is different because the secondary ions are released during a short time period of \( 1 \sim 100 \) ns when the primary ion beam is pulsed. There then follows a period of up to \( 100 \mu s \) during which the flight times of all the secondary ions are measured. Thus mass analysis of the complete spectrum from that pulse point occurs before the next primary pulse arrives. The duty cycle, i.e. the fraction of the time that the primary ion beam is playing on the sample, is typically only \( 10^{-4} \). The mass spectral information from each image pixel is summed and stored within the data system. The efficiency of collection of mass spectral information is therefore at a maximum. This simple example illustrates the main application area of surface chemical imaging where TOFMS has made a fundamental impact. Scanning mass spectrometers (mainly quadrupoles) have been used satisfactorily to produce large-area (1–2 mm) chemical spectra of surfaces since the early 1980s but the requirements for spatial information have led to dramatic developments in TOF instrumentation for SIMS, which we shall now examine in detail.

### 15.2 Instrumentation

#### 15.2.1 Primary Ion Probes

First let us look at the technologies now existing for producing finely focused primary ion probes and the way they have been developed for TOFSIMS. The brightest of all ion sources for laboratory use are the field emitters. This family of ion sources merits some discussion because virtually all modern TOFSIMS instruments utilize this type of source to realize the highest performance for surface imaging. The types of field-emitting ion sources used commonly are known as liquid-metal ion sources because they use a supported liquid-metal film as the field-emitting electrode. To understand how this comes about, it is instructive to consider the evolution of the emitter as the potential applied to the source is gradually raised. When the potential on the emitter is zero the liquid metal film conforms to the underlying electrode structure, as shown in Figure 42(a). As the potential on the emitter is raised, at first no current is observed. Only as the potential on the emitter exceeds a value of several kilovolts is emission observed to commence suddenly. This onset voltage coincides with a spontaneous change in the geometry of the liquid film into a cone shape (Figure 42b).

![Figure 42](image_url)

**Figure 42.** Evolution of the Taylor Cone as the applied voltage exceeds the onset voltage and the metal film suddenly forms a liquid cone and emits ions. See text for details. (Figure courtesy of Steven Thompson, Scientific Analysis Instruments Ltd, Manchester, UK.)

This is known after its discoverer as a “Taylor Cone” and it represents a geometry where surface tension and electrostatic forces are in equilibrium. The apex of the cone evolves to a point where its dimensions are atomic and here the cohesive forces acting between atoms in the liquid are reduced and the liquid is virtually torn asunder by the immense local electric field. At the same time electrons in the metal atoms can tunnel back into the liquid cone, leaving positive ions of metal atoms all formed within atomic dimensions (see Figure 42c). These ions form a diverging beam but, because they were formed in a region of a few nanometers, they can be brought back into focus using standard ion optical techniques to give a probe of \( \sim 50 \) nm in extent. For technological reasons
gallium metal is most commonly used in these sources but the move to more massive primary ion probes has rekindled interest in gold and bismuth.

Other primary ion sources used in TOFSIMS instruments are surface ionization sources for cesium and electron bombardment ion sources for inert gas ions. These also use conventional ion optical techniques to produce focused beams of ions. One ion optical technique that is particular to TOFSIMS concerns the production of short pulses of ions or ion packets. The design constraints on these ion packets are considerable: their spatial extent should not exceed that of a continuous beam, or spatial resolution will be lost; and their temporal extent has a major impact on the ultimate mass resolution available from the instrument because it directly influences the time period over which secondary ions are generated. Short pulses of ions are produced if the continuous beam enters a pair of electrostatic deflection plates energized with a potential of a few hundred volts such that the beam is deflected from the ion optical axis. If the potential on the plates is suddenly brought to zero and then returned to the original value, the beam will be brought back to the ion optical axis for a short time before being returned to the deflected state. If the duration of this voltage pulse is varied, then the length of the ion pulse can be controlled. Furthermore, if the ion beam forms a crossover within the deflection plates, this method of ion pulse blanking can be achieved without apparent movement of the ion probe. This so-called “motionless blanking” is illustrated in Figure 43.

Other schemes for the production of ion packets have been used successfully. If the beam is directed into a 90° ion mirror then the beam will only emerge along its chosen trajectory when a suitable deflecting potential is suddenly applied to the mirror electrode. Again, varying the duration of the applied potential can control the pulse width. These techniques can produce ion pulse widths in the range 3–100 ns. To achieve the highest mass resolution available from the TOF analyser, these pulse widths are still too long. The only option then is to use a method of electrodynamic pulse compression or “bunching”.

Bunching involves admitting a pulse of ions into a chamber consisting of two electrodes separated by a distance somewhat greater than the spatial extent, δz, of the pulse of ions while they are in flight. This is given from the product of the drift velocity of the ions, v, and the temporal pulse width, δt. At the instant the ions are between the two electrodes, the rearmost electrode suddenly has its potential raised by a few kilovolts, thus generating an electric field between the electrodes. The ions within the pulse gain an amount of energy from the field that depends upon their positions when the field was suddenly applied. So the ions at the rear of the pulse emerge from the chamber with a drift velocity somewhat greater than the ions at the front of the pulse. As the pulse of ions proceeds downstream toward the sample under analysis, it will become bunched up in time. The skill comes in ensuring that the pulse has its minimum width as it hits the sample. By techniques such as this, ion pulse widths as short as 800 ps can be achieved. The disadvantage of this method is that the pulse compression introduces a large chromatic spread into the beam. The chromatic aberration of the probe-forming lens limits the ultimate spatial resolution of the probe to a few microns.

When the ion source uses surface ionization of cesium as the primary ion, then mass filtering of the primary ion beam is not necessary. In general, however, it must be considered. Nonmass-filtered primary ion beams can lead to minor isotopes or impurities being admitted through the primary ion column. These will have drift velocities that differ from the primary species. Once an ion pulse packet is formed, dispersion in time will occur and pulse broadening will result, leading to a loss of resolution in the analyzer. This is a particular problem when using gallium.

Before moving on to consider the analyzer it is necessary to consider recent developments in the use of massive primary ions. As the primary ion impinges onto the sample surface it transfers its momentum into the lattice. Locally the lattice is in considerable turmoil but this diminishes as one moves away from the impact site. It is known that intact molecular ions are released several atomic diameters away from the impact site. As the impact site is approached and the extent of lattice vibration increases, then only molecular fragment ions are released. As the momentum transferred to the lattice is increased, by the use of high-mass primary ions, then the zone of formation of intact molecular

![Figure 43](image-url)
ions increases disproportionately. So the use of massive primary particles increases the relative yield of intact molecules from the surface. Originally, this led to the use of fission fragments from radioactive sources but recently the trend has been toward cluster sources from gold, Au\textsuperscript{2+}, and carbon, C\textsubscript{60}\textsuperscript{+}.

15.2.2 Mass Spectrometers

The properties of TOF mass analysers, which collect the secondary ions, are in many ways more straightforward than the primary probes that deliver them. The first stage of the mass spectrometer invariably consists of an accelerating field to collect the secondary ions. Two electrodes, the first of which is the electrode onto which the sample is loaded, form this accelerating field. The second electrode will form an annulus about the ion optical axis such that the secondary ions will be swept through the central aperture and on to the next stage of the mass spectrometer. Frequently this second electrode will have further apertures disposed at an angle of 30–40° to the ion optical axis to permit entry of the primary ion probes and a charge-neutralizing electron beam. The secondary ions are released from the surface with a kinetic energy of several electron-volts and a range of angles about the ion optical axis, so even after acceleration they form a cone of diverging ion trajectories as they pass out of the accelerating region. Typically they are then collected and focused into a well-collimated beam by an electrostatic lens. The secondary ions can then be left to drift in field-free space until they are detected. This simple type of mass spectrometer has two disadvantages. First, the small energy spread of the secondary ions cause temporal dispersion of the secondary ion packet as it travels down the drift tube, leading to a broadening of the detected signal and a loss of mass resolution. Second, the length of the flight tube sets a limit on the drift length of the ions after acceleration; again, this affects the mass resolution available.

If the ion trajectories could be folded back on themselves by an ion mirror or “reflectron” placed at the opposite end of the flight tube from the acceleration region, then the effective pathlength of the secondary ions could be greatly increased.\textsuperscript{[95]} This can be achieved by mounting a set of annular electrodes with suitable potentials in order to produce a constant retarding electric field on or near the ion optical axis. If the reflectron is mounted at a small angle to the ion optical axis, the ions leaving the reflectron and moving in the opposite direction to the ions entering will have diverging trajectories. This simplifies detection. The use of a reflectron has two benefits: it extends the effective pathlength of the secondary ions for a given flight tube and it provides a first-order correction for the ion energy spread. These benefits significantly improve the mass resolution available from the instrument.

Although the ion mirror reflectron is a popular device for the correction of ion energy spreads, other devices have been used. A remarkable instrument manufactured by the Physical Electronics Company (Eden Prairie, MN, USA) uses three 90° cylindrical analysers arranged in a way that not only provides a flat focal plane of time focus at the detector but also has spatial focusing properties. This means that the instrument can be used as a chemical imaging microscope where the spatial resolution is independent of the properties of the primary probe. The primary beam can therefore be set-up for the minimum pulse width to realize the maximum mass resolution from the analyser while still giving spatial resolution of the order of 10\textmu m.

15.3 Charge Neutralization\textsuperscript{[381]}

Many of the samples of interest to the surface chemist are likely to be poor electrical conductors, and yet the sample has to form one of the electrodes of the extraction system supporting an accelerating electric field of several kilovolts per centimeter. Furthermore, many secrets of the surface chemistry can be unraveled by studying both the positive and the negative secondary ions released from the surface. The clue to balancing the surface charge during analysis can be determined from other electric techniques such as X-ray photoelectron spectroscopy. It is known that effective charge balancing can be achieved by generating a cloud of very-low-energy electrons in the near-surface region of the sample. In some cases this cloud is confined by an axial magnetic field. Any change in the surface potential will result in a shift of the photoelectron peak. TOFSIMS instruments employ a strong extraction field for efficient collection of the secondary ions, so it is virtually impossible to direct a suitably low electron beam at the sample when the extraction field is applied. The technique used is to turn off the extraction field after every pulse of the primary ion beam, while the secondary ions are dispersing in time within the spectrometer. Then a short pulse of electrons is directed at the sample, after which the extraction field is restored and the next cycle commences.

If there is one type of application, that may be described as routine for TOFSIMS then it concerns investigation of the surface chemistry of synthetic polymers.\textsuperscript{[382]} There exists a considerable body of literature, that has been collected and collated into a series of handbooks. These discuss the interpretation of spectra in terms of the polymer properties, such as end groups, cross-linking and branching. The imaging capabilities of TOFSIMS are valuable when investigating fibers and composites.
Some of the most beautiful applications of TOF-SIMS have been demonstrated by the Physical Electronics Company (Eden Prairie, MN, USA) using the TRIFT II TOF imaging microscope.\(^\text{[383]}\) These applications have explored the full benefits of the instrumentation. Before looking at some of these examples, it is important to emphasize the requirement for sample preparation. Often the surface of interest is an internal surface requiring that the sample be mounted and then sectioned by a microtome in order to preserve the chemistry. Biological samples can, in principle, be analyzed using these methods but in this case the microtoming may have to be accomplished at low temperature and the sample kept at low temperature during the analysis. Such low-temperature sample-manipulating devices are available presently on TOFSIMS instruments but it serves to emphasize that the sample preparation can often take much longer than the analysis.

Clearly such instruments can be used to solve special problems as well as for routine use; because of this it is instructive to look at two or three different examples that represent the state of the art rather than discuss standard methods. Surface contamination of silicon wafers can be particularly difficult to detect, partly because the very high purity of materials used in this industry demands a low detection limit and partly because the regions of a silicon wafer available for analysis by a destructive technique like SIMS are so restricted. When the impurity of interest is iron, nominal mass 56 Da, this mass interferes with the abundant molecule \((^{28}\text{Si}_2)^+\) and it all looks like a lost cause. Fortunately, \(^{56}\text{Fe}^+\) has a significant mass defect of 7 mDa, whereas for \((^{28}\text{Si}_2)^+\) it is only 4 mDa; all organic interferences at that nominal mass have a positive defect.

Using the technique of electrodynamic pulse compression on the primary ion pulse to achieve a pulse duration of less than 1 ns, the spectrometer was able to resolve \(^{56}\text{Fe}^+\) from \((^{28}\text{Si}_2)^+\), demonstrating a mass resolution, \(m/dm\) of \(\sim 5000\). The area of the wafer sampled was only 40 \(\mu\text{m} \times 40 \mu\text{m}\). From the accumulated count rate and relative sensitivity measurements, it was possible to determine the surface concentration of iron to be at a level of less than \(1 \times 10^{10}\) atoms cm\(^{-2}\).

A second example further demonstrates the versatility of a good TOFSIMS instrument as a chemical microscope. Drug delivery systems frequently contain the active ingredient within a polymeric coating so that the release time of the active ingredient can be delayed following ingestion. These pellets form small spheres of 500 \(\mu\text{m}\) diameter held together by the coating, which is \(\sim 25 \mu\text{m}\) thick. The pellet was mounted, cross-sectioned and finally introduced for analysis. Remarkably, the intact molecular ion of the active ingredient, Metoprolol (MW of \(M + H = 268\) Da), was detected easily. Furthermore, the chemical image of the molecule could be seen surrounding a silicon core and extending uniformly out to the coating characterized by an ion map at 59 Da. This was later identified to be a fragment of ethylcellulose, the coating material. In this application, TOFSIMS has shown all the attributes for a true imaging chemical analyzer. The analysis proceeds directly on electrically insulating substrates, the charge balance being maintained by the use of a pulsed low-energy source of electrons. Detection of the intact molecule provides direct proof of the spatial distribution of specific organic species.

16 FUTURE ADVANCEMENTS AND CONCLUDING REMARKS

Most certainly, the recent trend of technical advances in TOFMS will continue in the years to come. TOF devices will become simpler to use and smaller in total size. Field-portable devices may ultimately be realized. TOF will continue to play an increased role in the realm of bioscience investigations. Improvements in sample preparation and SELDI technology will create even greater access to biological problems. SELDI-based bioassays may eventually find utility in research and clinical applications.

In terms of TOFMS technical innovations, future TOF devices will most likely obviate the requirement to adjust TLF parameters as a function of \(m/z\), while improving the accuracy of external standard measurements. The latter may be achieved through refinements in dynamic pulse focusing and/or orthogonal ion extraction. Improvements in sensitivity, especially for large ions, are also expected. Progress in CID/MS/MS technology, such as ion trap TOF, tandem TOF, and quadrupole–quadrupole TOF, will result in commercial devices compatible with ESI and MALDI ionization.

Indeed, the next millennium will see an increased role for TOFMS analysis. This technology will make significant contributions to the advancement of surface science, life science, elemental analysis, as well as inorganic and organic chemistry.

DEDICATION

This article is dedicated to my lovely wife Carla and my unborn child, Joseph Anthony or Leah Arabella. Their indelible patience and steadfast support were a continued source of inspiration.

Nuclear Magnetic Resonance and Electron Spin Resonance Spectroscopy: Introduction

Cecil Dybowski
University of Delaware, Newark, USA

1 Introduction

Nuclear magnetic resonance (NMR) is a phenomenon of certain nuclear isotopes, in which they absorb energy from a radiofrequency (RF) electromagnetic field. To evince this phenomenon, a nucleus must possess spin angular momentum, which – by virtue of the fact that it is charged – results in a nuclear magnetic moment that will couple to a magnetic field by the Zeeman interaction. (See Zeeman Interaction in Nuclear Magnetic Resonance by Dybowski.)

Protons and neutrons, as well as electrons, possess spin. Atomic nuclei are composites of protons and neutrons. Because of the coupling of the angular momenta of the nuclear particles, an atomic nucleus will have a nonzero spin if (1) the mass number \( A \) is odd, or (2) the mass number \( A \) is even and the atomic number \( Z \) is zero.\(^1\) Nuclei with an even mass number \( A \) and even atomic number \( Z \) will have a spin of zero in the nuclear ground state.

To create the energy states between which the transitions occur, the sample must be in a magnetic field, the strength of which determines the transition energy. Electron spin resonance (ESR) is a similar effect for electrons, as discussed by Giamello in Electron Spin Resonance Spectroscopy. The analytical uses of these techniques rely on the fact that the absorption frequency depends on the nature of the local environment in a manner easily correlated with chemical structure.

2 Discovery

Magnetic resonance was independently discovered immediately after World War II by research teams led by Zavoisky,\(^2\) Bloch,\(^3\) and Purcell.\(^4\) Zavoisky’s experiment demonstrated the effect known today as ESR (or paramagnetic resonance), while the experiments of Bloch and Purcell demonstrated the NMR effect for the proton. In part, these experiments resulted from developments in RF and microwave technology necessary for detection systems such as radar. The experiments were similar, in that they involved the absorption of energy by nuclear and electron spins bathed in a magnetic field. The possibility of such resonant absorption had been implied by earlier experiments on atomic beams in nonhomogeneous magnetic fields.\(^5\)

After these discoveries were announced, it was thought that the primary use of such magnetic resonance techniques would be the determination of fundamental constants of the nucleus or electron – the magnetogyric ratios – since the specific energy difference in a given magnetic field is determined by this property. However, it was soon discovered that NMR absorption depended not just on the magnetogyric ratio, but also slightly on the local environment.\(^6\) For example, the \(^14\)N resonance absorptions of NH\(_4\)NO\(_3\) were found to occur at two different energies in the same magnetic field.

3 Applications in Chemical Analysis

Of course, a technique to sense nuclei in different chemical environments immediately attracted the attention of chemists, who have always sought convenient ways to analyze materials, and the history of NMR spectroscopy as a convenient analytical tool in chemistry began with the discovery of the chemical shift. (See Chemical Shifts in Nuclear Magnetic Resonance by van Bramer.) The observation of spin–spin couplings in simple molecules demonstrated that the resonant absorption was also sensitive to the presence of other nearby nuclei,\(^9\) further enhancing the analytical utility of the technique. (See Scalar Couplings in Nuclear Magnetic Resonance, General by Karlsson.)

ESR spectroscopy, the outgrowth of Zavoisky’s experiment, showed a similar sensitivity to the local environment of the electron spin through the dependence of the electron g factor on local environment and hyperfine couplings to nuclear spins.\(^12\) Of course, to detect an ESR signal requires a material containing unpaired electron spins. Thus, the technique has become particularly valuable for analyses of materials containing radicals and unpaired electron spins.

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd
Within a decade of the discovery of NMR, proton magnetic resonance had assumed a prominent place in chemical analysis, particularly of organic materials. Chemists used it routinely to determine the structure of newly synthesized materials, and it was found that simple correlations of structure with NMR parameters allowed a picture of the molecule(s) in a sample to be pieced together from the proton NMR spectrum. The use of proton NMR spectroscopy in analysis of organic materials had a profound effect on the manner in which chemists did their work. By the 1960s, chemistry departments at universities and colleges had proton NMR instruments in routine use for analysis.

4 EXPANSION OF APPLICATIONS

During this period, the NMR properties of other nuclei were also being reported, pointing the way towards a more general use of NMR in the investigation of a broader range of materials. A particular development that has had wide application in chemical analysis came to fruition in the 1970s, with the ready availability of spectroscopy of nuclei such as $^{13}\text{C}$, $^{31}\text{P}$, and $^{29}\text{Si}$. Today we take for granted that modern NMR spectrometers are built to allow routine analysis of many different nuclear species, as discussed in Nuclear Magnetic Resonance Instrumentation by Neiss. However, early commercial spectrometers were single-frequency instruments, usually devoted to the proton. The analysis of other nuclei was the bailiwick of only a few specialists who had created instruments for detection of specific nuclei, usually with considerable effort. The introduction of commercial spectrometers to address the spectroscopy of nuclei other than protons, particularly $^{13}\text{C}$, reliably opened a wider use of NMR for analysis. (See Chemical Shifts in Nuclear Magnetic Resonance by van Bramer, and Parameters, Calculation of Nuclear Magnetic Resonance by Jameson, for example.)

For these other nuclear species (except tritium), the signal per nucleus is less intense than that of a proton (at fixed field), making it harder to detect. The often low natural abundance of many of the other isotopes having nuclear spins compounded this difficulty, and so analysis was tricky. The development of magnets of higher field and stability and of the Fourier transform technique to allow averaging to increase signal-to-noise ratio all addressed this problem, as discussed by Neiss in Nuclear Magnetic Resonance Instrumentation. By the mid-1970s it was likely that analysis of nuclei such as $^{13}\text{C}$ was an integral part of a routine analysis of some newly created material. Nowadays, analyses of many different nuclei are easily carried out with modern instrumentation.

The simplicity of correlations between NMR parameters and chemical structure is the principal feature that has made it such a useful technique. (See Parameters, Calculation of Nuclear Magnetic Resonance by Jameson.) As interest in more and more complex materials has grown, the NMR spectra obtained have become increasingly more and more complex. As a result, techniques for spectral assignment became the focus of activity in NMR research. The development of selective decoupling experiments led to studies of how one might use the inherent NMR properties to manage information available from NMR spectra. More versatile RF electronics allowed the development of pulse decoupling methods that used power more efficiently and provided better decoupling to simplify spectra. With the advent of sophisticated computer systems and more control of the spectrometer’s properties, NMR spectroscopists developed experiments to manage the information, such as multidimensional NMR spectroscopy for correlation of NMR parameters, as discussed in Byrd’s article, Two-, Three- and Four-dimensional Nuclear Magnetic Resonance of Biomolecules. The result was simplification of the interpretation of the often complex spectra. An understanding of the way these experiments worked resulted in the development of a plethora of techniques now in common use for spectral simplification and analysis, so that nowadays one may do a series of NMR experiments on a complex material to provide a detailed chemical structure.

Articles by Eriksson Nuclear Magnetic Resonance and Nucleic Acid Structures, Yuan Magnetic Resonance Angiography, Menon Magnetic Resonance Imaging, Functional, Richards Multinuclear Magnetic Resonance Spectroscopic Imaging, Smith Magnetic Resonance in Medicine, High Resolution Ex Vivo, McCarthy Nuclear Magnetic Resonance in the Analysis of Foodstuffs and Plant Materials and Fan Nuclear Magnetic Resonance in Analysis of Plant Soil Environments discuss a variety of applications of magnetic resonance to medicine and biology, an important use of the technique. However, magnetic resonance has found many industrial applications, for example in the analysis of polymers (Nuclear Magnetic Resonance, Imaging of Polymers by Hafner, Nuclear Magnetic Resonance, Solid State in Analysis of Polymers and Rubbers by Mirau), coatings (Bran-dolini, Nuclear Magnetic Resonance of Coating and Adhesive Systems) and fossil fuels and hydrocarbons (Miknis, Nuclear Magnetic Resonance Characterization of Petroleum). It is also used in fields such as environmental monitoring (MacFall, Nuclear Magnetic Resonance for Environmental Monitoring) and drug
detection (Dawson, *Nuclear Magnetic Resonance Spectroscopy for the Detection and Quantification of Abused Drugs*).

5 APPLICATIONS TO SOLIDS

In the 1960s, 1970s and 1980s, NMR spectroscopists revisited the study of solid materials, where analysis of chemical structure had been limited by inherent NMR properties of solids, particularly dipole–dipole coupling and quadrupolar coupling. The development of techniques to decouple nuclei efficiently and manipulate the information in the NMR spectrum brought the analysis of solids to a further level of refinement. One technique that has become routine uses rapid spinning about an axis inclined at the “magic angle” to the magnetic field to produce a spectrum of spins like $^{13}$C that is qualitatively similar to a solution spectrum. However, the development of techniques to emulate solution-state spectra was not the only development in solid-state NMR. The analysis of materials in the solid state gives more detailed pictures of the electronic properties. Today, for example, the measurement of properties such as: the coupling of a spin $I > 1/2$ to the electric-field gradient at the nuclear site through its electric quadrupole moment, or the tensor properties of the chemical shift, is used to identify a material. Various aspects of the application of NMR to solids and solid-like materials are discussed in the articles by Freude *Quadrupolar Nuclei in Solid-state Nuclear Magnetic Resonance*, Canet *Relaxation in Nuclear Magnetic Resonance*, General, McGregor *Solution Nuclear Magnetic Resonance: Spin-1/2 Nuclei Other than Carbon and Proton*, Gerald *Solid-state Nuclear Magnetic Resonance*, Neue *Nuclear Magnetic Resonance in Metals Analysis*.

6 CURRENT STATUS OF MAGNETIC RESONANCE

In the articles in this section, you will find explanations of how magnetic resonance is used in analysis throughout chemistry and allied sciences. Some articles focus on the esoterica of the technology of NMR spectroscopy, while others discuss applications of NMR spectroscopy to analysis of specific types of materials. We have tried to strike a balance between topics that emphasize the constant development of the technology of magnetic resonance and the applications of the technique that make it useful for the chemist interested in identification of materials. Inevitably, some topics will be overlooked or emphasized less; there are many other topics that could, no doubt, be included, but we hope the sampling in the encyclopedia will provide an overview of the many ways magnetic resonance is currently used.

One thing is clear in all these examples: the ability of magnetic resonance spectroscopy to provide analytical information on a wide variety of materials in a format that is convenient to interpret in terms of structure and chemical function. This is the central feature of the magnetic resonance spectroscopic technique – one that makes it a primary analytical technique in the arsenal of tools chemists use to define the systems they produce in virtually every venue in which a chemist is active – geology, biology, industrial production, or laboratory-bench research.

REFERENCES

Carbon-13 (13C) nuclear magnetic resonance spectroscopy (NMR) is the measurement of the precession or resonance frequencies of the net magnetization for 13C nuclei whose individual magnetic moments have been oriented in a strong magnetic field. Nuclei differing in their electronic shielding precess about the magnetic field at different Larmor or resonance frequencies. A high-power radiofrequency (rf) pulse is used to perturb the magnetization vectors from their equilibrium distribution, generating an observable transverse magnetization. Precession of this net magnetization vector about the static magnetic field induces a voltage into the NMR probe coil. Relaxation pathways promote the repartitioning of the individual magnetic moments to their equilibrium Boltzmann distributions and a dephasing of the individual magnetization vectors in the transverse plane. This signal is detected as a function of time through a phase-sensitive receiver, digitized and Fourier transformed (FT) into a frequency domain spectrum. The NMRs, referenced relative to the resonance frequency of a standard are shifted in a manner characteristic of hybridization of the atom, electronegativity of the substituents attached and the steric environment of the nucleus. These shifts typically follow a standard set of rules and thus spectra can be simulated either empirically through measurement of the additive effects of substituents or through ab initio and semi-empirical computational methods. Scalar couplings to directly attached hydrogen-1 (1H) nuclei split resonance lines into \((n_{1H} + 1)\) lines and require the use of broadband 1H decoupling to remove this splitting for sensitivity enhancement. The presence of attached or nearest neighbor 1H atoms also provides a means of enhancing the signal intensity of 13C spectra and for selective observation of 13C signals through polarization transfer. Multidimensional NMR experiments are available which permit the 13C–13C or 13C–1H correlations as well as a means of measuring \(^{3}J_{\text{CH}}\) couplings.

Analysis of samples can be done without the need for internal standards or calibration standards since NMR signals are directly proportional to the moles of analyte present and there are no response factors or absorptivities to be determined for quantitative analysis. Although 13C NMR spectroscopy is widely used and is a very powerful structural technique in organic and polymer chemistry, the technique suffers from an inherent lack of sensitivity due to a natural abundance of only 1.1 percent and a small magnetogyric ratio \((\gamma_C)\). Long relaxation times present in small molecules undermine the quantitative accuracy of this method or require lengthy amounts of instrument time to acquire an NMR spectrum. Quantitative results can be obtained with the selection of appropriate experimental parameters often combined with the use of relaxation agents.

1 INTRODUCTION

Carbon-13 (13C) NMR is the measurement of the precession or resonance frequencies of the net magnetization for 13C nuclei whose individual magnetic moments have been oriented in a strong magnetic field. Nuclei differing in their electronic shielding precess about the magnetic field at different Larmor or resonance frequencies. A high-power rf pulse is used to perturb the magnetization vectors from...
their equilibrium distribution, generating an observable transverse magnetization. Precession of this net magnetization vector about the static magnetic field induces a voltage into the NMR probe coil. Relaxation pathways promote the repartitioning of the individual magnetic moments to their equilibrium Boltzmann distributions and a dephasing of the individual magnetization vectors in transverse plane. This signal is detected as a function of time through a phase-sensitive receiver, digitized and FT into a frequency domain spectrum. The NMRs, referenced relative to the resonance frequency of a standard are shifted in a manner characteristic of hybridization of the atom, electronegativity of the substituents attached and the steric environment of the nucleus. These shifts typically follow a standard set of rules and thus spectra can be simulated either empirically through measurement of the additive effects of substituents or through ab initio and semi-empirical computational methods. Scalar couplings to directly attached hydrogen-1 (1H) nuclei split resonance lines into \(n_{1H} + 1\) lines and require the use of broadband 1H decoupling to remove this splitting for sensitivity enhancement. The presence of attached or nearest-neighbor 1H atoms also provides a means of enhancing the signal intensity of 13C spectra and for selective observation of 13C signals through polarization transfer. Multidimensional NMR experiments are available which permit the 13C—13C or 13C—1H correlations as well as a means of measuring 4JCH couplings.

Analysis of samples can be done without the need for internal standards or calibration standards since NMR signals are directly proportional to the moles of analyte present and there are no response factors or absorptivities to be determined for quantitative analysis. Although 13C NMR spectroscopy is widely used and is a very powerful structural technique in organic and polymer chemistry, the technique suffers from an inherent lack of sensitivity due to a natural abundance of only 1.1 percent and a small magnetogyric ratio \(\gamma_{C}\). Long relaxation times present in small molecules undermine the quantitative accuracy of this method or require lengthy amounts of instrument time to acquire an NMR spectrum. Quantitative results can be obtained with the selection of appropriate experimental parameters often combined with the use of relaxation agents.

### 1.1 Development of Carbon-13 Nuclear Magnetic Resonance Spectroscopy

While the concept of nuclear magnetism had been discussed in the early part of this century,\(^1\) the nearly simultaneous reports of Bloch\(^5\) and Purcell\(^4\) contained the first experiments to demonstrate the phenomenon of magnetic resonance. With improvements to the homogeneity of the external applied magnetic field, resolved 1H-NMR spectra of simple molecules such as ethanol could be acquired, displaying the potential of NMR as a tool for the structural analysis of organic molecules.\(^6\) However, it wasn’t until 1957 that the first study of 13C NMR spectra of organic compounds appeared in the scientific literature.\(^7\) Development of this method suffered largely from the low sensitivity inherent in the NMR experiment, hindered by the low natural abundance of the 13C isotope and its small magnetogyric ratio relative to 1H nuclei (1 : 4). In addition, 13C signals were split into multiplet structures due to attached protons, further reducing the signal-to-noise ratio (S/N) of the NMR signal. The introduction of broadband decoupling of 1H nuclei,\(^7\) the advent of pulse FT NMR experiments\(^8\) and the development of higher magnetic field NMR spectrometers resulted in the emergence of 13C-NMR as a routine analytical tool for the structural analysis of organic materials. Pulsed experiments also made viable the concept of signal averaging,\(^12\) the accumulation and addition of multiple scans to improve sensitivity of the NMR experiment. This averaging has the effect of summing coherent resonance signals while the random noise found in an NMR spectrum does not, resulting in an increase in the S/N of a spectrum proportional to (number of scans)\(^1\). Once all of these gains were realized, the acquisition of 13C spectra became a routine event and the study of organic molecules using NMR rapidly grew to encompass most areas of chemistry and molecular biology.

Further refinement of NMR instrumentation, particularly in the area of superconducting magnets, extensive use of computers, and the development of multiple pulse NMR experiments has further expanded the utility of 13C-NMR experiments. Introduction of polarization transfer methods such as the Insensitive Nucleus Enhancement via Polarization Transfer (INEPT)\(^13,14\) and Distortionless Enhancement via Polarization Transfer (DEPT)\(^15,16\) multiple pulse sequences improved the sensitivity of the 13C experiment through the transfer of spin distribution information from attached protons with the potential to increase the 13C signal intensity by \(\gamma_{H}/\gamma_{C}\), which is very close to four. The DEPT sequence can also be used to determine the multiplicity through spectral editing based on modulation of the carbon signal by scalar couplings to attached protons. Use of these pulse methods has also been extended to multidimensional NMR experiments in which 13C signals are correlated to other nuclei with methods such as heteronuclear correlation (HETCOR) for the correlation of 13C signals to those NMRs of attached protons and incredible natural abundance double quantum transfer experiment (INADEQUATE), which is a homonuclear 13C—13C correlation experiment.
1.2 Applications Summary

Applications of $^{13}$C-NMR spectroscopy, facilitated by the continued development of larger superconducting magnetic fields, encompass most organic chemical systems, from small molecules to synthetic and biological polymers with molecular weight ranges from a few to millions of daltons. Use of this technique is focused on the wealth of information contained in the NMR spectrum, revealing not only structural identity, but quantitative composition, conformational properties, molecular dynamics and reaction mechanisms. In many applications, $^{13}$C-NMR is the only analytical tool capable of supplying quantitative structural information in a nondestructive manner.

NMR spectroscopy is a principal characterization tool for the organic chemist. A $^{13}$C NMR spectrum serves as a fingerprint of molecular structure, with signals due to specific functional groups occurring in regions of the NMR spectrum established through decades of experimental study. Acquisition of a $^{13}$C spectrum for a small molecule (MW $\approx$ 400 daltons) routinely requires less than an hour, in part due to higher magnetic fields and the proliferation of automated NMR spectrometers. From a simple one-dimensional (1-D) $^{13}$C spectrum, one can obtain an approximate measure of sample purity, as well as an assay of the types of functional moieties present. With more sophisticated polarization transfer methods, the number of protons attached to each carbon can be determined. The measurement of scalar $^3J_{CH}$ couplings can provide information on molecular conformation of the molecules under study.\(^{(17,18)}\) Multiple quantum methods such as $^{13}$C-$^{15}$C homonuclear correlation spectroscopy enable the spectroscopist to determine the carbon connectivities and thus the molecular framework of an unknown structure.\(^{(19,20)}\) Reaction mechanisms and dynamic processes can also be examined through $^{13}$C NMR methods. The larger spectral dispersion is especially favorable for the study of exchange phenomena.\(^{(21,22)}\) Line-shape analysis as a function of temperature can be used to determine the rate of a dynamic process such as conformer exchange and the thermodynamic stability of each isomer.\(^{(23–25)}\) With appropriate care in sample temperature measurement, an analysis of the line-shape or kinetic rate constants using NMR yields the Arrhenius activation energy ($E_A$) and the free enthalpy of activation ($\Delta G^*$). Isotopic labeling is also a valuable tool for elucidating mechanisms by analyzing the placement of the isotope in the product formed in the reaction. Isotope labels used in $^{13}$C-NMR experiments include $^{13}$C, $^{15}$N and $^2$H.

NMR is often used to determine the structure and conformational properties of natural products such as terpenes,\(^{(26–28)}\) steroids,\(^{(29,30)}\) carbohydrates and polysaccharides,\(^{(31–34)}\) nucleotides,\(^{(35–37)}\) and proteins,\(^{(38–42)}\) $^{13}$C-NMR of natural products synthesized under controlled conditions with $^{13}$C-labeled starting materials reveals the route by which these products are created biologically.\(^{(43–45)}\) Since samples can be examined in a variety of solvents, over a wide range of temperature, and with numerous experimental methods, the structural parameters which can be obtained on biomolecules are extensive. For example, the $^{13}$C chemical shift of the anomeric carbon in polysaccharides is not only sensitive to the type of adjacent monosaccharide, but also to which position on that residue it is attached and to its anomic configuration, $\alpha$ or $\beta$. Selective nuclear Overhauser effect (NOE) experiments and HETCOR techniques contribute through-space distances and dihedral angles which are used in conjunction with molecular modeling techniques to determine the three-dimensional (3-D) structure of biological molecules.

Perhaps the most insightful studies using $^{13}$C-NMR spectroscopy are in the study of polymer systems. NMR is the only analytical method capable of providing information on the monomer composition, conformation, configuration, monomer distribution and polymer dynamics in situ and nondestructively. Analysis ranges from synthetic polymers with a typically regular microstructure to heterogeneous biopolymers such as polysaccharides derived from higher-order plants. NMR spectroscopy has been used extensively to determine the compositional and configurational parameters in synthetic polymers.\(^{(46–49)}\) $^{13}$C chemical shifts are sensitive to parameters such as the tacticity of consecutive monomers and the distribution of different monomers in mixed polymer systems.\(^{(50)}\) A classic example is in the spectrum of polypropylene. The methyl signal appears as a complex series of lines from changes in monomer sequence configurations up to four units away, resulting in shifts of the resonance and providing enough data to perform sequence analysis at the heptad level. Observed shifts are also sensitive to the structure of neighboring monomers in the polymer chain and, from these shifts, a statistical model can be derived for monomer sequence distributions in a polymer. $^{13}$C relaxation studies are effective measures of the segmental mobility and functional group dynamics in polymer systems.\(^{(50,51)}\)

Some examples can be found where $^{13}$C-NMR has been used for quantitative purposes.\(^{(52–56)}\) It is not considered a routine method for quantitative analysis due to relaxation effects, peak enhancement from NOE, offset effects, and the cost of NMR spectrometers. Often relaxation enhancement agents are necessary to shorten $^{13}$C relaxation times and quench NOEs for quantitative purposes.\(^{(53,54,57)}\) Of course this sort of sample contamination is not acceptable if limited sample is available for analysis by other methods. Many examples exist in the literature in which $^{13}$C NMR is used semiquantitatively to determine the molar composition of synthetic...
polymers, polysaccharides and other multicomponent systems where normal wet chemical or chromatographic methods may not be applicable. Internal standard methods can also be used to determine weight percent concentrations of analytes in solution if the solvent is transparent to the NMR spectrometer.

2 THEORY

$^{13}$C nuclei are spin 1/2. The physical basis of the NMR experiment discussed here is applicable to other nuclei with a spin quantum number $I = 1/2$, such as $^1$H, $^{19}$F, $^{31}$P or $^{29}$Si. Understanding the magnetic resonance phenomenon is a complex quantum-mechanical problem and no attempt is will be made here to offer a complete theoretical description, but a general physical chemical description is given to familiarize the reader with the basic principles of NMR. Numerous treatises are available which explain such theoretical formulations as density matrix theory, product operator formalisms or Bloch equations for the description of the magnetic resonance phenomenon.\(^{[58-61]}\)

Important aspects of $^{13}$C-NMR for the analytical chemist are the concept of chemical shift and the ability to determine quantitatively the constituent groups in a molecule. Chemical shift is the primary source of structural information, i.e. what type of functional groups are present in a sample and how are they connected to each other. Quantitative accuracy depends primarily on relaxation processes that return magnetization to equilibrium. These topics are presented in detail to provide the chemist with a practical understanding of their use and the limitation of NMR in quantitative analysis.

2.1 Physical Description of the Magnetic Resonance Phenomenon

Nuclei with either odd atomic number or mass possess the property of nuclear spin, denoted by the spin quantum number $I$. Isotopes such as $^{12}$C$_{\alpha}$, which has both an even atomic mass and atomic number, do not have this property and are not NMR-active. This property of spin gives rise to a magnetic moment ($\mu$) for the nucleus since the oscillation of an electrical charge generates a magnetic field. In the absence of any external magnetic field, $\mu$ has no preferential orientation, a net equilibrium magnetization ($M_e$) does not exist, and there is no observable NMR signal. Placing the nuclei in a strong magnetic field orients the individual moments either with the external field in a low-energy state ($\alpha$) or against the applied field in a high-energy state ($\beta$). These magnetic moments precess about the external magnetic field at a frequency that depends on the size of the external field, known as the Larmor frequency, $v_0$. The quantum numbers of energy levels that nuclear spins may occupy are defined by $m$ as shown in Equation (1).

$$m = I, I – 1, I – 2, \ldots – I$$

$^{13}$C nuclei have $I = 1/2$, for which there are two energy levels for $^{13}$C with an energy separation defined in Equation (2):

$$\Delta E = \frac{\gamma_C B_0 h}{2\pi}$$

where $\gamma_C$ is the magnetogyric ratio for $^{13}$C ($6.7263 \times 10^7$ rad T$^{-1}$ s$^{-1}$), $B_0$ is the external magnetic field strength, and $h$ is Planck’s constant ($6.6256 \times 10^{-34}$ J s). This is illustrated in Figure 1. For a 11.744 Tesla magnet with a $^1$H resonance frequency of 500.1 MHz, the energy-level separation for $^{13}$C is defined by Equation (3):

$$v_0 = \frac{\gamma_C B_0}{2\pi}$$

which corresponds to 125.7 MHz. This frequency is the rate of precession about the external field and that frequency corresponding to the energy necessary to cause a transition from one energy level to another. The populations of the $\alpha$ and $\beta$ energy levels follow a Boltzmann distribution shown in Equation (4):

$$\frac{N_\alpha}{N_\beta} = e^{\frac{\Delta E}{kT}} = e^{\frac{\gamma_C B_0 h}{kT2\pi}}$$

in which $k$ is the Boltzmann constant ($1.38044 \times 10^{-23}$ J K$^{-1}$) and $T$ is the sample temperature in kelvins. At

![Figure 1](energy_level_diagram.png)
CARBON-13 NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY

$T = 298 \text{ K}$ and $B_0 = 11.744 T, N_a/N_p$ is 1.00004, indicating the very small difference in equilibrium populations of the energy levels available for observation in the NMR experiment. This equation demonstrates that the population difference is dependent on $B_0$, being larger in a large magnetic field. Thus, the higher field increases the sensitivity of the NMR experiment.

The basic NMR experiment is shown in Figure 2. When a sample is exposed to a pulse of rf radiation at $v_0$ with an intensity given by the field, $B_1$, the individual magnetization vectors begin to precess about this field as well as the external field $B_0$. This additional precession effectively tilts $M_z$ away from $B_0$ through an angle $\theta$, defined in Equation (5):

$$\theta = \gamma c B_1 t_p$$

where $t_p$ is the pulse duration time for $B_1$. Once in the transverse $(x, y)$ plane, $M_t$ precesses about $B_0$ at its individual precession frequency, $v_i$, which is the sum of $v_0$ and the chemical shift effect described in section 2.4. This precession, still about $B_0$, generates a voltage in the NMR receiver coil modulated at $v_i$, and is detected as a function of time as shown in Figure 2(d). After digitization, the signal is analyzed with Fourier transformation to present the frequency components corresponding to the precession frequencies of individual $^{13}$C species, shown in Figure 2(e).

During precession of $M_t$, numerous processes occur. Chemical shift effects cause nuclei of different electronic structure to precess at different rates, some faster and some slower than $v_0$. Spin–spin relaxation processes cause the various components of $M_t$ to dephase in the $x, y$ plane, which gives rise to the finite width of the resonance line in the NMR spectrum. Spin-lattice relaxation also allows the individual $\mu_i$ to return to their equilibrium Boltzmann distributions. The resulting time-dependent signal is continually decaying due to relaxation and is termed the free induction decay (FID). Any scalar, dipolar or quadrupolar couplings also modulate the magnetization, observed as splittings or broadening of the resonances in the frequency spectrum. Once $M_z$ has been re-established, the experiment can be repeated and the resulting signals added to increase sensitivity of the experiment.

Pulse NMR spectroscopy essentially detects the signals from all nuclei that resonate at or near the frequency of

![Figure 2](image-url)
the high-power rf pulse. This high-power pulse has the effect of exciting a wide range of spectral frequencies determined by the relationship shown in Equation (6):

\[
S(w) = \frac{1}{2\pi p} \int_{-\infty}^{\infty} s(t)e^{-iwt} dt \tag{7}
\]

where \( S(w) \) is the frequency domain function and \( s(t) \) is the time domain function. Current computer software uses the fast Fourier transform (FFT)\(^{(61)}\) to complete this transformation rapidly to produce a frequency-domain spectrum with resonances at positions corresponding to their precession frequencies and whose intensities are proportional to the number of nuclei of each type in the sample.

### 2.2 Interactions Present in Carbon-13 Nuclear Magnetic Resonance Measurements

Magnetic resonance involves numerous interactions that must be described to obtain a complete picture of the information in an NMR spectrum. Several of these interactions will be discussed in further detail in following sections (chemical shift and NOE). The major interactions of interest are summarized in Table 1. The Zeeman interaction exists for all nuclei with a nonzero spin quantum number and is the interaction of the applied field, \( B_0 \) with \( \mu_i \), as discussed in section 2.1. The size of this interaction is linearly proportional to \( B_0 \), resulting in an increasing separation of energy levels with an increase in \( B_0 \).

In solution \(^{13}\)C-NMR, the dominant relaxation pathways are dipolar, but the fluctuating interaction of the quadrupole moment of quadrupolar nucleus with an electric field gradient can affect relaxation pathways of attached nuclei or those in close spatial proximity. In the case of \(^{14}\)N, this can lead to broadening of \(^{13}\)C spectral lines arising from directly attached nuclei while increasing the time for attached \(^{13}\)C nuclei to return to their equilibrium spin distributions. Scalar couplings of quadrupolar nuclei with \(^{13}\)C nuclei are also possible, typically observed for \(^2\)H nuclei which have a small value for \( \chi \) or a high degree of symmetry about the quadrupolar nucleus.

The chemical shift interaction is the most significant component of the NMR experiment, as it is the most diagnostic of the chemical environment around a nucleus, providing a spectral resonance for each chemically distinct nucleus in a molecule. It can best be described as the difference in Larmor frequencies of nuclei with differing electronic (chemical) environments. Effects of the electronic environment can shield or deshield the nucleus from \( B_0 \) relative to another resonance, in essence adding or subtracting an additional \( B_i \) magnetic field, so that the precession frequency of a chemically distinct nucleus, \( v_i \), is not exactly the same as \( v_0 \). This effect is defined by a magnetic shielding constant (\( \sigma \)). This constant has contributions from diamagnetic and paramagnetic shielding, magnetic anisotropy from surrounding nuclei, ring currents, conjugation, steric effects, electric fields, and intermolecular effects such as hydrogen bonding and solvation. Shifts from \( v_0 \) are in the order of several kilohertz (kHz) as compared to the 20 to 200 MHz range typical of \(^{13}\)C Larmor frequencies at current magnetic field strengths. A more detailed discussion of the chemical shift can be found in section 2.4.
Scalar or spin–spin couplings result from interactions between adjacent magnetic dipoles that perturb the local magnetic fields around a nucleus. Since these dipoles may be aligned with or against \( B_0 \), they may increase or decrease the effective field at the nucleus being observed, causing a shift from \( v_i \). Since an adjacent dipole for \(^{13}\text{C} \) is most likely \(^1\text{H} \) nuclei, the states, \( \alpha \) and \( \beta \), have almost equal probabilities, this coupling splits the \(^{13}\text{C} \) resonance into two lines of equal intensity centered on \( v_i \). Scalar couplings are indirect spin–spin couplings and occur through chemical bonds. A direct dipolar coupling occurring through space is also possible, but with rapid isotropic motion found in solution NMR, this coupling is averaged to zero. In solid-state NMR this direct coupling is a dominant effect and can be used as a means of efficient polarization transfer from abundant \(^1\text{H} \) nuclei to dilute \(^{13}\text{C} \) nuclei, enhancing the sensitivity of the \(^{13}\text{C} \) NMR experiment. In the \(^{13}\text{C} \) experiment, heteronuclear scalar couplings to protons are removed with broadband \(^1\text{H} \) decoupling to remove the \(^1\text{H} \)--\(^{13}\text{C} \) splittings. This simplifies the spectra and improves the sensitivity of the experiment. Scalar couplings are also used for polarization-transfer experiments to improve sensitivity or to modulate the \(^{13}\text{C} \) resonances depending on the number of directly attached \(^1\text{H} \) nuclei.

Dipolar couplings are direct spin–spin couplings that exist through space and not through chemical bonds as in the case of indirect scalar couplings. The local field around a \(^{13}\text{C} \) nucleus created by a nearby \(^1\text{H} \) dipole is shown in Equation (9):

\[
B_{\text{LOC}} = \pm \frac{\mu_0 (3 \cos^2 \theta' - 1)}{r_{ij}^3}
\]

where \( r_{ij} \) is the internuclear distance and \( \theta' \) is the angle between \( r_{ij} \) and \( B_0 \). The dependence of \( B_{\text{LOC}} \) on \( \theta' \) in a rapidly tumbling molecule results in a rapid modulation of the local field and provides an effective pathway for relaxation. The strong dependence on \( 1/r_{ij}^3 \) means this is a localized phenomenon. Thus \(^{13}\text{C} \) nuclei with directly attached \(^1\text{H} \) nuclei will have more rapid and efficient relaxation pathways. Further discussion of dipolar interactions and relaxation will be presented in sections 2.5 and 2.7.

### 2.3 Heteronuclear Decoupling

Interaction of the numerous dipoles present in an organic molecule can complicate a \(^{13}\text{C} \)-NMR spectrum and make structural identification a complex, if not impossible, task. Resonance splittings and line-width broadening due to scalar couplings decrease the sensitivity of the NMR experiment. For \(^{13}\text{C} \) nuclei, directly attached protons are the dominant partner in scalar couplings, though longer-range couplings through multiple bonds also produce smaller couplings. The scalar coupling between two dipoles is designated \(^nJ_{ij}\) where \( n \) is the number of bonds connecting the two spins, and \( i \) and \( j \) are the identities of the scalar coupled nuclei. A typical carbon–proton one-bond scalar coupling, \(^1J_{\text{CH}}\), is on the order of 125 to 150 Hz. Longer-range couplings diminish rapidly to several Hz for a \(^3J_{\text{CH}}\) coupling. The number of lines, \( L \), in a multiplier from a \(^{13}\text{C} \) resonance is given in Equation (10):

\[
L = 2nI + 1
\]

where \( n \) is the number of attached nuclei and \( I \) is the spin quantum number of those spins. As an example, a methylene group has two hydrogens, both with a magnetic dipole and an \( I = 1/2 \), and would be split into three lines separated by \(^1J_{\text{CH}}\). A fully proton coupled \(^{13}\text{C} \) NMR spectrum is shown in Figure 3(a) for abietic acid, a tricyclic rosin acid isolated from pine tar. A methylene signal at 51 ppm is shown in the insert, with both the splitting and a significant broadening of the resonance due to longer-range couplings and dipolar couplings. The size of scalar couplings is dependent primarily on hybridization of the carbon atom (\( sp^3 \), \( sp^2 \) or \( sp \)) and the relative electronegativity of any substituents attached to the atom. While higher-order couplings may be positive or negative, \(^1J_{\text{CH}}\) values are always positive.

While there is useful information in \( C,H \) scalar couplings, removing them is necessary to simplify \(^{13}\text{C} \) spectra to permit interpretation of the underlying spectrum in terms of chemical groups. This process of heteronuclear decoupling yields a spectrum denoted as a \(^{13}\text{C}(^1\text{H} \) \) spectrum, where the nucleus in brackets is decoupled in the experiment.

There are numerous methods of spin decoupling. The most widely used is broadband decoupling. A second rf pulse, \( B_2 \), is applied to the sample at the \(^1\text{H} \) Larmor frequency with sufficient power to cover the entire range of \(^1\text{H} \) Larmor frequencies. The power required to do this increases with \( B_0 \). At 500 MHz, a decoupler field strength of 6 kHz would be required to decouple nuclei effectively over the entire range of carbon chemical shifts. To minimize the power required to decouple protons, methods have been developed using composite pulse decoupling (CPD) schemes which change the phase of the rf pulse, creating rapid spin transitions between \( \alpha \) and \( \beta \) energy levels.\(^{62,63}\) As long as the rate of transition exceeds the maximum scalar coupling found in a molecule, the \(^1\text{H} \) spins are effectively decoupled from the \(^{13}\text{C} \) spins. With this type of experiment, effective heteronuclear decoupling can be achieved at very low rf power levels, minimizing frequency offset problems and sample heating seen at higher power levels.

Experimentally, decoupling only needs to be done during the period in which the \(^{13}\text{C} \) signal is acquired.
Figure 3  $^{13}$C NMR spectra of abietic acid (C$_{20}$H$_{30}$O$_{2}$), a terpene resin acid acquired with: (a) single-pulse excitation and no $^{1}$H decoupling; (b) single-pulse excitation with $^{1}$H decoupling during acquisition only; (c) single-pulse excitation with $^{1}$H decoupling during acquisition and relaxation delays; (d) DEPT experiment with $^{1}$H decoupling during acquisition only. Expansions shown in (a) and (b) are of the same methyne signal at 51 ppm plotted on the same horizontal scale.
A $^{13}\text{C}$($^1\text{H}$) NMR spectrum of abietic acid is shown in Figure 3(b) using low-power CPD. Comparison to the fully $^1\text{H}$ coupled spectrum of Figure 3(a) demonstrates the enhancement in sensitivity and simplification of the NMR spectrum when decoupling is used. While the effects of scalar couplings are lost in decoupling experiments, there are other methods to retrieve the multiplicity of information they carry. In the inset of Figure 3(b), the methyne resonance of Figure 3(a) is shown in expansion. In addition to collapsing the doublet to a singlet, there is a very dramatic decrease in line width. This narrowing is the result of removing unresolved long-range scalar couplings of only a few hertz and residual dipolar couplings whose effects are to broaden the resonance line.

Enhancement of the $^{13}\text{C}$ NMR signal is also obtained if the $^1\text{H}$ $B_2$ field remains on during the relaxation or delay period between signal acquisitions. A comparison of Figure 3(c) with Figure 3(b) demonstrates the substantial gain in signal intensity when the $B_2$ field is left on during the relaxation delay after acquisition. This results from the NOE generated between the $^1\text{H}$ and $^{13}\text{C}$ nuclei. Section 2.5 explains this effect and its potential use in structural studies. Enhancement is dependent on the number of protons attached and the internuclear distance to the $^{13}\text{C}$ nucleus. Use of NOEs increases sensitivity, but often precludes quantitation of dissimilar functional groups because NOE enhancement rates differ from group to group.

Other methods of decoupling include selective decoupling (to establish connectivity between $^{13}\text{C}$ and $^1\text{H}$ nuclei), continuous wave (CW) decoupling, and off-resonance decoupling. In selective decoupling experiments, use of a low-power $B_2$ field whose frequency is matched to a specific $^1\text{H}$ resonance affects only $^{13}\text{C}$ resonances directly bonded or strongly dipolar coupled to the irradiated $^1\text{H}$ nucleus. These resonances will have NOE enhancement or decoupling, a fact that enables assignment of $^{13}\text{C}$ resonances from correlation with proton resonances. Repeated use of this kind of experiment allows one to assign the coupled resonances with a series of experiments. This technique is not used nowadays as often as it once was because multidimensional NMR methods have been developed that provide this same coupling information for all resonances in one experiment. CW decoupling is not often used in solution NMR as the power required is large on high-field spectrometers. This causes sample heating which can detune the NMR probe and cause broadening due to magnetic field inhomogeneities introduced through heating the sample. It is routinely used in solid-state NMR to remove the strong direct dipolar couplings in solid samples. In this case, heteronuclear dipolar couplings are very large, typically in the 20–80 kHz range for which low-power heteronuclear decoupling would be ineffective. Off-resonance decoupling is completed with the $B_2$ decoupling field moved away from the $^1\text{H}$ Larmor frequency, which retains the C,H couplings but scales them depending on the difference between their precession frequency and the applied $B_2$ field frequency. Off-resonance decoupling has been replaced by the more rapid and sensitive methods found in coherence-transfer techniques discussed in section 2.6.

### 2.4 Chemical Shifts in Carbon-13 Nuclear Magnetic Resonance Spectroscopy

The utility of the NMR experiment arises from the ability to distinguish one atom from another in the same molecule. This is the single most important capability of the technique, to study chemical structure at the atomic level. While the Zeeman interaction determines the average Larmor frequency of a nuclear type, i.e. $^{13}\text{C}$ versus $^1\text{H}$, in a given magnetic field, local electronic shielding around a specific $^{13}\text{C}$ nucleus diminishes the strength of the $B_0$ field at a specific nucleus, thus shifting its Larmor frequency, $v_i$. The chemical shift interaction, as shown in Table 1, contains a tensor element in its Hamiltonian. The chemical shift is an interaction determined by the shape and orientation of the molecular framework relative to $B_0$. In the extreme narrowing limit where random molecular reorientation is rapid, the chemical shift is determined by the average of the principal elements of this tensor—the isotropic value; this is the position of the resonance in a solution. On the other hand, solid-state measurements retain this quality of spatial chemical shift and require the use of high-speed sample spinning techniques to facilitate spectral observation of the isotropic-like spectrum.

Numerous factors can affect shielding, and thus the position of a resonance, including bonding, hybridization, functional groups, steric interactions and motion. The shift of the Larmor frequency of a specific nucleus from a defined reference position is the chemical shift, $\delta$.

#### 2.4.1 Introduction to Chemical-shift Concepts

The shielding of a nucleus by electrons is proportional to the strength of the applied magnetic field, $B_0$. This proportionality factor is the magnetic shielding constant, $\sigma$. The effective field at nucleus $i$ can be defined in terms of $\sigma$ and $B_0$, so that Equation (3) can be written as in Equation (11):

$$v_i = \frac{\gamma C}{2\pi} B_0 (1 - \sigma_i)$$

where $v_i$ is the observed Larmor frequency for a nucleus and $\sigma_i$ is the magnetic shielding constant for that nucleus. Each chemically different nucleus will have a unique
where $v_i$ is the resonance frequency of nucleus $i$, $v_{ref}$ is the resonance frequency of TMS or other known reference signal. As the difference $(v_i - v_{ref})$ is in hertz, the shift of Larmor frequencies is small and the ratio in Equation (12) is Hz/MHz or parts-per-million. Resonances to the left of the position (of higher Larmor frequency) in a spectrum have positive values of the chemical shift, and those to the right, negative values. Use of the ppm scale permits comparison of spectra acquired at different magnetic field strengths, since the fractional frequency shift should be independent of the magnetic field strength. For example, a resonance with $v_i = 7645$ Hz acquired at a $B_0$ field of 7.05 T ($v_1 = 75.45$ MHz), would have $\delta = 101.33$ ppm. On an instrument with $B_0 = 11.744$ T ($v_1 = 125.72$ MHz), the same resonance would have $v_i = 12739$ Hz and from Equation (12), $\delta = 101.33$ ppm. Resonances with positive chemical shifts are said to be deshielded relative to TMS (and in a nomenclature derived from experiments in which swept magnetic fields were used, downfield of TMS), and those with negative values relative to TMS are said to be more shielded (or in the older nomenclature, upfield of TMS). From Equation (11), $\sigma_i$ values for deshielded resonances are smaller than those for more shielded nuclei. The terms upfield and downfield are also used in discussions of resonance positions relative to other signals in the NMR spectrum. The carboxyl resonance of acetic acid at 179 ppm is said to be downfield of the carboxylate resonance of methyl acetate at 171 ppm.

Resonance positions are sensitive to many external factors, and parameters such as temperature, pH, solvent and reference signal must routinely be cited when reporting chemical shifts. Both temperature and pH can affect the shift of resonance lines relative to a reference, particularly in aqueous samples, and should be controlled. Nuclei can also have different chemical shifts in different solvents through solvation effects and polarity of the solvent. An advantage of $^{13}$C-NMR is the wide dispersion of chemical shift values, providing well-resolved NMR spectra. The standard range of chemical shifts is from $\pm 10$ to 230 ppm, though there are materials that resonate outside this range such as transition-metal complexes, molecules with strongly electronegative substituents, paramagnetic centers and other structural features which distort the electron density around a $^{13}$C nucleus.

### 2.4.2 Factors Affecting Chemical Shift Positions

Any structural feature which affects the electron density around a nucleus will affect $\sigma$, and as a result, $\delta$. These include hybridization of the atom, charge density, substituent electronegativity, inductive effects, ring currents, steric interactions, unpaired electrons, hydrogen bonding, isotope effects, intermolecular interactions, solvent, temperature, pH and conformational properties of the molecule. Hybridization of the $^{13}$C nucleus is primarily responsible for determining the chemical shift range for a specific nucleus. In general, sp$^3$ atoms resonate furthest upfield (at lowest frequency) in the $\pm 10$ to 110 ppm region, sp$^2$ atoms in the 110 to 230 ppm region and sp atoms in the 80 to 120 ppm region of the NMR spectrum. Theoretical approaches to calculating $\sigma_i$ are difficult and are not precise, due to the wide range of contributions to shielding and the complexity of calculating such calculations even for relatively simple classes of molecules.

For the organic chemist, the most important contributions to the chemical shift are the electron distribution around the nucleus, characterized by $\sigma_{dia}$ and $\sigma_{para}$, and neighboring-group effects including magnetic anisotropy, electric field effects, intermolecular interactions and ring-current effects in $\pi$-bonding groups. Any calculation of $\sigma$ may be expanded to include terms for these effects, as shown in Equation (13):\(^{22,44}\)

$$\sigma_i = \sigma_{dia} + \sigma_{para} + \sum \sigma_N + \sum \sigma_R + \sum \sigma_e + \sum \sigma_l$$

where $\sigma_{dia}$ is the contribution from isotropic circulation of the spherically symmetrical electron cloud to shielding, $\sigma_{para}$ is the nonspherically symmetric contribution, $\sigma_N$ is the magnetic anisotropy contribution from neighboring atoms, $\sigma_R$ represents ring current effects, $\sigma_e$ are contributions from electric fields from polar groups in the molecule, and $\sigma_l$ is a result of intermolecular contributions resulting from hydrogen bonding or solvation. The first three terms are applicable for all observed carbon resonances, while the other terms depend on the structure being studied and whether, for example, arene rings are present to contribute to $\sigma_R$ or polar groups such as carbonyls are present to contribute intramolecular electric fields. Paramagnetic shielding is considered the dominant term for shielding in $^{13}$C-NMR.

Isotopic circulation of the electrons surrounding a nucleus generates a spherically symmetrical field, creating a local magnetic field opposite in orientation to $B_0$. This field is proportional to the electron density around the nucleus and results in an upfield shift...
of the resonance line as this local density increases. Diamagnetic shielding is inversely proportional to the distance between the nucleus and surrounding electrons, with electrons contributing the dominant shielding term. Local contributions to this shielding from neighboring atoms are also included in calculations of the shielding parameter. Numerically, $\sigma_{\text{dia}}$ is a large term in the magnetic shielding, but is not considered to be the dominant factor in determining overall shielding and chemical shift of a $^{13}\text{C}$ nucleus.

Paramagnetic contributions arise from nonsymmetrical electron circulation around a nucleus as a result of chemical bonding and bond hybridization effects. Shielding of this nature can be described with Equation (14):\(^{66}\)

$$
\sigma_{\text{para}} = -\frac{e^2 h^2}{m^2 e^2} \Delta E^{-1} r_{2p}^{-3} [Q_{AA} + \sum Q_{AX}] 
$$

(14)

where $\Delta E$ is the mean electron excitation energy, $r_{2p}$ is the average distance between the nucleus and a $2p$ electron, and $[Q_{AA} + \sum Q_{AX}]$, the charge density bond order matrix. Contributions to paramagnetic shielding depend on accessibility of low-level excited states, the effective nuclear charge, number of electrons in $p$ orbitals, and their distances from the nucleus. This latter contribution is considered the primary contribution to $\sigma_{\text{para}}$, producing the wide range of chemical shifts in $^{13}\text{C}$ spectra.

Neighboring anisotropic effects contribute to shielding of a nucleus due to the circulation of electrons on nearby atoms and of the currents generated through bonding electrons. This shielding term is defined in Equation (15):\(^{22,67,68}\)

$$
\sigma_{\text{N}} = \frac{1}{3K_{\text{NB}}^{-3} \Delta \chi_B (1 - 3 \cos^2 \theta_B)} 
$$

(15)

where $K_{\text{NB}}$ is the distance between the nucleus and dipole $B$, $\Delta \chi_B$ is the anisotropic term for the magnetic susceptibility of dipole $B$, and $\theta$ is the angle defined by the vector between the nucleus and dipole $B$ and the symmetry axis of dipole $B$. A summation over all nuclei bound to the atom being observed and other nuclei in close proximity is done to account for the contribution of this term. From Equation (15) it is evident that this contribution to shielding depends only on the distance between the dipole and nucleus and the angle $\theta$, while it is not dependent on the nature of the nuclei under observation.

Increasing electronegativity of a substituent produces a downfield shift of the $\alpha$ carbon signal due to the inductive nature of these functional groups. Attraction of electron density to the electronegative group reduces the electron density at the carbon nucleus, resulting in a deshielding of the nucleus. Unshared electron pairs also produce a downfield shift in a $^{13}\text{C}$ resonance, as their presence increases the contribution from $\sigma_{\text{para}}$ to chemical shielding. Electron deficiencies found in positively charged species, also result in a downfield shift of $^{13}\text{C}$ resonances. Multiple bond conjugation effectively increases the shielding of the central nuclei in the delocalized bond environment, yielding an upfield shift of the affected resonances. Steric effects arise as a result of the close spatial proximity of atoms in a molecule. Repulsive forces from spatially close atoms may produce either upfield or downfield shifts, dependent on the molecular geometry. For example, $\gamma-\delta$-gauze effects in alkanes typically shift $^{13}\text{C}$ resonances upfield, but this effect is dependent upon spatial orientations and can be either shielding or deshielding. Functional groups containing ionic charge also have electric fields that can distort the electron density and bond polarizability of neighboring carbon atoms, producing both up- and downfield resonance shifts.

Many factors influence the chemical shift of a nucleus. Rationalization of chemical shift positions based on a limited number of factors may result in erroneous attribution of a shift. Competing contributions between two or more structural features may make the interpretation of the spectrum in structural terms ambiguous. Molecular geometry, motion and exchange processes can also complicate spectra, making interpretation on first principles difficult. To understand an NMR spectrum fully, it is often beneficial to examine known samples of similar structure. In the following sections, representative examples of $^{13}\text{C}$ chemical shifts are presented, along with a survey of methods for calculating chemical shifts.

### 2.4.3 Representative Examples of Carbon-13 Chemical Shifts

An immense amount of literature exists about $^{13}\text{C}$ chemical shifts of organic molecules and an impossible task would be to summarize that literature completely. Numerous reviews and compendia of NMR spectra are available to provide more comprehensive tabulations.\(^{51,22,66,71-79}\)

Normal chemical shift ranges for organic functional groups are shown in Figure 4. The ranges presented are for carbon atoms $\alpha$ to the functional group or for the underlined carbon atom in the functional group in the left column. Other carbons in a molecule with this functional group will have resonances consistent with their structural identity, though shifted in a way that depends on the long-range shift effects of the functional group, typically up to four carbons away.

The $^{13}\text{C}$ NMR spectrum is, in the most simplified view, considered to have four regions where signals can be found and easily classified. The region from zero to 35 ppm is where most aliphatic carbons with only carbon
or hydrogen substituents resonate. Functional groups on \( sp^3 \) carbons are found in the 40–110 ppm region, carbons with one or two oxygens resonating further downfield than carbons with nitrogens. Aromatic and olefinic \( sp^2 \) carbons appear in the 110–150 ppm region, the perturbation of \( p \) shell electrons producing a deshielding effect. Carbonyl resonances are found in the 150–220 ppm region of the spectrum, with aldehydes and ketones found shifted further downfield than carboxylic acids, esters and amides. Table 2 contains \(^{13}C\) chemical shifts of a representative group of compounds from many areas of chemistry.

Some general observations can be discussed and a few representative spectra shown to illustrate the technique. Linear aliphatic groups contain distinct signals for a methyl at 14 ppm, a methylene \( \alpha \) to the methyl at 23 ppm, \( \beta \) at 32 ppm and internal methylenes in the chain at 29 ppm. The spectrum of a mixture of \( C_8 – C_{10} \) straight-chain carboxylic acids is shown in Figure 5(a), displaying a typical aliphatic pattern and a carboxylic acid resonance at 180.3 ppm. The peak at 34 ppm in the aliphatic region is the carbon \( \alpha \) to the carbonyl group, owing to the downfield-shift contribution of the carbonyl. Other aliphatic compounds, i.e. amines, alcohols, halides,

(continued overleaf)
esters, ketones, etc. have similar aliphatic patterns, with the exception of the carbon α to the functional group. There is always some shifting due to longer-range effects, and any carbons that are part of a functional group such as an aldehyde carbonyl will be shifted.

The $^{13}$C spectrum of a seaweed galactan is shown in Figure 5(b). The signals around 100 ppm arise from the acetal carbons of the pyranose rings which have two oxygen atoms bound to them. The region from 85 to 60 ppm contains signals from carbons with a single oxygen attached either as a secondary ether linkage or as a primary or secondary alcohol. The trend is for primary to be farthest upfield, with increasing substitution causing a downfield shift. The $^{13}$C-NMR spectrum of a terpene mixture is shown in Figure 5(c), exhibiting a typically crowded aliphatic region from 10 to 50 ppm, olefinic and aromatic resonances from 110 to 150 ppm and various carbonyl signals in the 170–190 ppm region. Figure 5 also shows a division of the $^{13}$C-NMR spectrum into four general regions, given below the spectral axis. For most organic compounds, the $^{13}$C shifts are predictable, and a general conclusion about functionality can quickly be made by noting the presence of signals in these four regions. Inclusion of transition metals or the presence of charge can complicate the interpretation of spectra since these structural moieties can shift $^{13}$C signals to regions where they would not typically be present or to regions well outside the normal 230 to $-10$ ppm spectral region.

### 2.4.4 Review of Methods for Calculating Chemical Shifts

Predicting or simulating $^{13}$C-NMR spectra as an aid to the assignment of a spectrum or for developing a qualitative description of an organic structure can be approached

Development of additivity rules is an empirical exercise based on the examination of an appropriate number of model compounds through a regression analysis to determine substituent effects on 13C chemical shifts. Numerous schemes exist (depending on the class of chemical compounds being examined) and current development in this area focuses on both new classes of compounds and computer methods for developing additivity relationships. Grant and Paul first pioneered these principles in their development of additivity rules for linear and branched hydrocarbons. This work reported that the chemical shift of a carbon nucleus could be determined through the relationship (Equation 16):

\[ \delta_{\text{obs}} = -2.3 + n_a S_a + n_\beta S_\beta + n_\gamma S_\gamma + n_\delta S_\delta + n_\epsilon S_\epsilon + C \]  

(16)

where \( S_a \) is the increment in chemical shift due to the \( a \) substituent and \( n_a \) is the number of these substituents \( a \) to the carbon in question. \( C \) is an additional term related to the substitution of the nucleus observed and the most highly substituted \( a \) carbon, and \(-2.3\) is the reference chemical shift of unsubstituted methane. The incremental shift parameters for the Grant–Paul equation are given in Table 3.

Further development of this relationship was reported by Linderman and Adams, in a paper in which they extended the relationship to that shown in Equation (17):

\[ \delta_C(k) = B_S + \sum_{M=2}^{4} D_M A_{SM} + \gamma_S N_\gamma + \delta_S N_\delta \]  

(17)

where \( \delta_C(k) \) is the chemical shift of the \( k^{th} \) carbon, \( B_S, A_{SM}, \gamma_S \) and \( \delta_S \) are constants from Table 4.

For these constants \( S \) is the number of carbons bonded to the nucleus whose shift is being calculated, \( D_M \) is the number of carbons bonded to \( k \) with \( M \) carbons attached, with \( N_\gamma \) and \( N_\delta \) representing the number of carbons \( \gamma \) and \( \delta \) to carbon \( k \) respectively. A comparison of results obtained using this method, the Grant–Paul equation, prediction from a spectral database software program and experimentally determined results for 3-methylpentane is shown in Figure 6. As seen in this figure, all three methods provide reasonable estimates for \( \delta \) values of the example hydrocarbon. These rules were subsequently extended to substituted hydrocarbons using an equation of the

same form as Equation (16), but with the coefficients shown in Table 5 for some common organic functional groups. Predictive models of this type have been extended to cyclic alkanes and substituted alkenes and substituted benzenes. Table 5 contains the additivity constants for calculating the chemical shifts of substituted benzenes. A base shift of 128.5 ppm is used for all positions, and the appropriate shift contributions are added or subtracted from this number for each substituent on the aromatic ring for each carbon in the aromatic ring. Comparison of calculated and experimental values for p-fluorotoluene is shown in Table 6. These methods employing empirically derived relationships provide reasonably accurate estimates of $^{13}$C chemical shifts and are widely used as interpretative aids for structural analysis. Progress in the areas of chemical shift prediction and additivity relationships has focused on the use of different computational methods to derive the correlations necessary for prediction within classes of compounds. Recent studies have employed computerized methods using multilinear regression (MLR) analysis or artificial neural networks (ANN) for the development of additivity relationships. Creation of large chemical databases containing known chemical structures or fragments with correct chemical shift assignments has fostered development of computer software capable of finding structures to match an experimental spectrum, predict the structure of an unknown from a spectrum or construct an NMR spectrum from an input structure. These methods are rapid and can be tailored to the chemistry of interest.

Commercial packages also “learn” to predict spectra or structures as the basis set of structures for prediction is expanded. Empirical methods are rapid and provide the most utility for analytical spectroscopy.

Ab initio and semiempirical methods are used to solve Schrödinger’s equation for a molecule, a description of the energy states in the system. Chemical shifts are calculated after adding the perturbation effects of $H_0$, and related to the total energy of the molecule and nuclear magnetic moment mathematically. The electronic environment around a nucleus has an orientation in the molecular framework and is sensitive to the direction of the applied magnetic field, thus the chemical shift must be described as a tensor to account for all possible orientations of the molecule and the magnetic field. In liquids and gases with isotropic molecular motion, this directional dependence is averaged out and the observed chemical shift is the average of the principal tensor elements.

Treatment of magnetic shielding in a molecule has been done through numerous theoretical frameworks, ranging from Rayleigh–Schrödinger perturbation theory\(^{112–113}\) to self-consistent field (SCT) theory.\(^{114–117}\) An exact solution of Schrödinger’s equation for typical organic molecules is not possible and approximate wave functions are used to obtain solutions. Linear combinations of atomic orbitals (LCAOs), are used to derive a basis set of molecular orbitals. The orientational dependence of the chemical shift of a carbon in a molecule in a magnetic field cannot be adequately described with normal wave functions because they cannot describe the gauge invariance of these functions. A larger basis set could be used, but this approach would not be viable for larger molecules. The introduction of gauge independent atomic orbital methods (GIAO), which use local gauge origins for LCAOs, made possible a comprehensive framework for calculation of chemical shifts.\(^{118–122}\)

Additional methods such as individual gauge for localized orbitals (IGLO) and localized orbitals, localized origin (LORG) are also available and are computationally faster methods.\(^{123–128}\) However, development and applications of the GIAO abound in the literature, focusing on optimization of calculations and the application to progressively larger molecules.\(^{128–137}\)

Semiempirical methods introduce approximations to the formalisms used in ab initio methods to simplify expressions for describing the energies and associated wave functions of complex molecular systems. Theoretical approximations for describing diamagnetism were first described by Pople and still referred to in current studies of $^{13}$C chemical shifts.\(^{138,139}\) Various approaches to semiempirical calculations exist based on bond polarization theory,\(^{140}\) average excitation energy approximations,\(^{141}\) valence bond theory,\(^{142}\) and empirical parameterization from previous experimental results.\(^{143–145}\)

While more complex and with the potential to relate chemical shifts to molecular structure at a basic level, these methods are more qualitative in their results, as a result of assumptions and approximations required to make computation manageable. Difficulties also arise in accounting for all the potential electronic and nuclear interactions that may exist in the molecular spin systems. Coupled with this problem are any potential internuclear perturbations from solvents or through interactions such as hydrogen bonding. While these methods are developing rapidly as computer calculation speeds increase and theoretical treatments are refined, this methodology is not generally of practical use for the practicing analytical chemist completing routine structural analysis. However, ab initio and semiempirical methods can provide insight into structural phenomena such as folding, binding, and the orientation of the chemical shift tensor with respect to the molecular framework, an insight into the electronic environment around a nucleus.

2.5 Nuclear Overhauser Effects

When heteronuclear dipolar couplings exist between two spins, their relaxation behavior is interrelated and changes in one spin reservoir will have an effect on the entire coupled system. In $^{13}$C-NMR spectroscopy, the dominant dipolar couplings occur between $^{13}$C nuclei and their directly attached $^1$H spins, serving as the primary relaxation pathway for protonated $^{13}$C spins. Use of heteronuclear decoupling to suppress scalar couplings...
causes a saturation of the $^1$H spin system, altering the energy-level populations for $^{13}$C-$^1$H dipolar coupled systems. This perturbation and resultant enhancement of the $^{13}$C-NMR signal is known as the NOE.$^{(146–149)}$

2.5.1 Origin of the Nuclear Overhauser Effect in Heteronuclear Spin Systems

Dipolar coupling of nuclear spins alters the energy-level diagram shown in Figure 1 to that for a two-spin system shown in Figure 8. In this spin system, there are four single-quantum nuclear-spin transition probabilities with $P_{13}$ and $P_{24}$ corresponding to $^1$H spin transitions and $P_{12}$ and $P_{34}$ denoting the corresponding $^{13}$C spin transitions. Single-quantum transitions are those responsible for spin-lattice relaxation processes (see section 2.7). The transitions $P_2$ and $P_0$ represent double-quantum and zero-quantum transitions respectively, which cannot be directly excited with rf pulses or directly observed in the NMR spectrum. Through dipole–dipole relaxation processes, these two transitions do occur and are not affected by other relaxation processes that affect the single-quantum transitions.

Saturation of $^1$H transitions with a continuous rf pulse, as found in $^{13}$C-NMR experiments where $^1$H spins are decoupled to remove scalar couplings, produces a nonequilibrium spin distribution. Continuous saturation produces the state where $P_{13} = P_{31}$ and $P_{24} = P_{42}$ so that these relaxation processes cannot re-establish thermal equilibrium populations in each of the four energy levels.

![Figure 8](image)

Figure 8 Energy-level diagram for a two-spin, A,X system with single quantum transitions shown in solid lines and zero ($P_0$) and double ($P_2$) quantum transitions represented with broken arrows.

The effect of this saturation is equalize the populations so that $N_1 = N_3$ and $N_2 = N_4$. At this point, the zero- and double-quantum dipolar relaxation processes, with $P_2$ and $P_0$ transition probabilities, begin to establish equilibrium, population distributions. Since $N_2/N_4$ is less than that found at equilibrium, repopulation of $N_1$ through the $P_2$ pathway proceeds, decreasing $N_4$ and increasing $N_1$. The net effect is to increase the population differences $N_3 - N_4$ and $N_1 - N_2$. $^{13}$C signal intensities are directly related to these population differences, so that any increase in these differences will produce an increase in the $^{13}$C signal intensity. However, the zero-quantum relaxation pathway, with transition probability $P_0$, is also active, attempting to re-establish the $N_2$ equilibrium population while reducing the $N_1$ population. This would decrease the $(N_1 - N_2)$ and $(N_3 - N_4)$ population differences and reduce the $^{13}$C NMR signal intensity.

A competition exists between these two processes, one which would increase the $^{13}$C signal intensity and one which would decrease the intensity. Molecular motion determines which process is more effective and, consequently, whether the NOE will produce a larger $^{13}$C signal. For molecules with short molecular correlation times ($\tau_C$), the $P_2$ transition probability prevails and the $^{13}$C signal enhancement is positive. Since this is a double-quantum pathway, the dipolar modulation frequency required to initiate these transitions is the sum of Larmor frequencies of the nuclei involved ($\nu_H + \nu_C$) in the process. The zero-quantum transition has a much smaller frequency requirement ($\nu_H - \nu_C$) and is the favored transition when $\tau_C$ is longer, indicating slower molecular tumbling. Small organic molecules generally have a positive signal enhancement, while larger molecules, such as biopolymers, may have zero or negative NOEs. Since both $P_2$ and $P_0$ depend on both the Larmor frequencies and $\tau_C$, NOEs are magnetic-field-dependent. Since $\tau_C$ is not field-dependent, increasing magnetic field strengths may produce smaller or negative NOE values when $(\nu_H + \nu_C)\tau_C \approx 1$.

The NOE enhancement factor ($\eta$) is dependent on the magnetogyric ratios of the nuclei involved in the dipolar coupled processes, as shown in Equation (18): 

$$\eta_{(NOE)} = \frac{\gamma_H}{2\gamma_C}$$

which for $^{13}$C($^1$H) experiments is 1.988. For a $^{13}$C spectral resonance with a full NOE, the signal intensity would then be (Equation 19): 

$$I = I_0(1 + \eta_{(NOE)})$$

where $I$ is the NOE-enhanced intensity and $I_0$ is the equilibrium peak intensity. Full enhancement is realized when dipolar relaxation is the principal spin-lattice
relaxation mechanism for a molecule tumbling in the extreme-narrowing region of motion. In many cases, full enhancement is not obtained due to numerous effects such as multiplex effects on NOE rates and transition probabilities.

Measurement of NOE values are carried out by several methods, the most common involving the acquisition of two spectra, one with the $^1$H decoupler on during the delay between the end of spectral acquisition and the next observation pulse, and the second with the decoupler off during this period. The delay between acquisition should be longer than five times the longest spin-lattice relaxation time to allow the $^{13}$C spin system to reach thermal equilibrium. The spectral intensities are ratioed to determine the NOE enhancement factor. Samples should be prepared in fully deuterated solvents and care should be taken to eliminate paramagnetic impurities such as O$_2$ from the solvent.

2.5.2 Applications of Nuclear Overhauser Effect Measurements

Heteronuclear NOEs are used to enhance the signal sensitivity for nuclei with a small $\gamma$ and/or a low isotopic natural abundance, both categories include $^{13}$C nuclei. Other nuclei also exhibit strong NOEs, such as $^{15}$N, $^{29}$Si and $^{31}$P. Since some of these nuclei have negative magnetogyric ratios, their NOE enhancements may be negative and unfortunate selection of experimental conditions can actually destroy sensitivity or completely suppress resonances. As the NOE values obtained for different structural moieties and molecules of differing size may vary, the use of NOEs often precludes accurate quantitative analysis and transforms $^{13}$C-NMR into a semi-quantitative or qualitative method. As seen in Figure 3(c), the spectrum of abietic acid acquired with steady-state NOE has a greater S/N than those acquired (a and b) where NOE was not active.

Selective NOE measurements are a valuable aid in structural elucidation and conformational analysis. Use of $^{13}$C measurements is limited to nonprotonated atoms since $^1$H--$^{13}$C NOEs are dominated by directly attached protons and no spatial information is likely to be obtained from protonated carbon resonances. Dipolar relaxation rates have a $1/r^6$ dependence, making the NOE phenomenon a local one. Selective saturation of a single $^1$H resonance will provide an enhancement of $^{13}$C nuclei within effectively 2.5 Å of the proton under irradiation. This should limit enhancement to directly bonded spins or those in close spatial proximity. The former serves as an assignment aid, while analyzing the NOEs of the latter can be used to determine molecular conformation or association between different molecules. Less-than-complete enhancement can be used to determine internuclear distances. Hydrogen bonding can be explored through saturation of proton resonances and searching for enhancements in the $^{13}$C resonances of atoms which may participate in bonding with the protons. NOE measurements have also found application in determining the chain microstructure in synthetic polymers.

The low sensitivity inherent in $^{13}$C-NMR limits the use of selective NOE measurements. Polarization transfer methods have been developed which provide proton multiplicities and increased sensitivity to replace NOE methods. $^{13}$C NOE measurements have largely been usurped by a combination of $^1$H detected heteronuclear ($^{13}$C--$^1$H) and homonuclear ($^1$H--$^1$H) 2-D (two-dimensional) measurements which are much more rapid and contain substantially more information for the study of molecular conformation and dynamics. The development of high-field superconducting NMR spectrometers has made acquiring and interpreting homonuclear $^1$H--$^1$H NOE data less complicated and more informative than heteronuclear NOE methods. Multidimensional HETCOR experiments designed to provide carbon–proton bonding networks have replaced selective NOE experiments for both assignment confirmation and, through measurement of $^3$J$_{CH}$ couplings, a wealth of conformational data can be determined in one spectrum. These techniques are part of a class of pulse sequences called inverse methods since the NMR spectrum is detected as a $^1$H signal to improve sensitivity. Pulsed polarization transfer methods can also be used for multiplicity determinations in $^{13}$C spectra. Development of these techniques has limited the scope of applications for $^{13}$C--$^1$H NOE measurements to instances where results of $^1$H experiments are ambiguous.

2.6 Coherence Transfer in Carbon-13 Nuclear Magnetic Resonance Measurements

The multiplicities of $^{13}$C-NMR signals are important structural parameters for completing spectral resonance assignments. Examination of a $^1$H-coupled $^{13}$C spectrum to determine the number of attached hydrogens can be complicated by overlapping resonance splitting patterns, as seen in Figure 4(a) and also suffers from an inherent insensitivity due to the loss of resonance intensity when sharp single lines are split into multiplet structures. Alternative methods for determining the multiplicity of $^{13}$C lines rely on pulsed polarization transfer to increase $^{13}$C signal sensitivity while the NMR signals are modulated as a result of $^3$J$_{CH}$ couplings to produce multiplicity information. Numerous polarization-transfer methods exist, though two nonselective methods that find the most utility in $^{13}$C-NMR are INEPT, and DEPT. Polarization transfer is somewhat analogous to the NOE experiment since both processes lead to an enhancement of $^{13}$C-NMR signals, the former using scalar...
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

Couplings through direct bonding pathways in contrast to the through-space dipolar couplings active in NOE. As a consequence, only $^{13}$C nuclei with directly bonded protons will be observable in the spectrum obtained with INEPT, DEPT and other polarization-transfer schemes. Polarization transfer is completed using a series of pulses to effect transfer through spin reorientation, rather than saturation of $^1$H energy levels with continuous irradiation, as is done in the NOE experiment. The pulse sequence required to effect transfer is shown in Figure 9(c) and compared to a standard 1-D $^{13}$C/$^1$H pulse sequence with NOE in Figure 9(a). Polarization-transfer sequences of this type are also the fundamental units of heteronuclear multidimensional NMR sequences discussed in section 2.8.

The basic premise of polarization transfer lies in the ability to change $^{13}$C spin distributions ($\alpha$ and $\beta$) to that of directly attached $^1$H spins at equilibrium. Observable $^1$H magnetization is generated in the transverse plane with a nonselective pulse. Precession of the magnetization vectors occurs for a time period of $1/4J_{CH}$. This time delay serves to label the $^1$H magnetization components by the orientation ($\alpha$ or $\beta$) of their coupled $^{13}$C spin components. A refocusing/inversion pulse is then applied to both $^1$H and $^{13}$C spin systems, refocusing the $^1$H chemical shifts through a spin echo and inverting the $^{13}$C spin populations, effectively changing the identity and precession direction of the resulting magnetization vectors. After a second $1/4J_{CH}$ delay, the spin-labeled magnetization vectors are $180^\circ$ out of phase with each other. A final $^1$H $90^\circ$ pulse returns the magnetization to the $z$ axis. However, the initial energy-level populations have been changed so that level 2 in Figure 8 has been switched with that of level 4. The population differences for the allowed $^{13}$C transitions, $1 \rightarrow 2$ and $3 \rightarrow 4$ are greater and $^{13}$C signals are enhanced by the ratio defined

---

**Figure 9** Pulse sequences used to acquire (a) a $^{13}$C NMR spectrum with NOE and, (b) an inversion-recovery experiment for measurement of $T_1$, (c) a refocused INEPT spectrum with a positive phase for CH and CH$_3$ groups and a negative phase for CH$_2$ groups and (d) the sequence for acquiring a 2-D $^{13}$C-$^1$H HETCOR spectrum.
This ratio is 3.98 for $^{13}$C and $^1$H nuclei. A refocusing period and heteronuclear decoupling of $^1$H spins produces a sensitivity-enhanced $^{13}$C spectrum in which methylenes are phase inverted relative to methyne and methyl signals, and quaternary signals are suppressed. Delays between successive scans can also be made shorter as $^1$H relaxation now limits the pulse repetition rate.

Owing to the sensitivity of the refocused INEPT to the delay periods around the second refocusing pulses, the DEPT sequence is more commonly used in sensitivity enhancement and multiplicity determinations. Similar in nature to INEPT, this sequence is less sensitive to refocusing delays and can be used to generate subspectra of differing multiplicities. The second $^1$H π pulse in the INEPT sequence is replaced with a pulse of varying flip angle $\theta$. Three spectra are acquired with $\theta$ set to 45°, 90° and 135°. The spectrum with $\theta = 90°$ has only methylene carbon signals, the $\theta = 135°$ spectrum will have positive methyl and methyne peaks and negative phase methylene peaks. The three spectra are mathematically added and subtracted to generate the following subspectra:

- DEPT90 CH subspectrum.
- DEPT45 − DEPT135 CH$_2$ subspectrum.
- DEPT45 + DEPT135 − (0.707 * DEPT90) CH$_3$ subspectrum.

A common practice is to acquire only the DEPT spectrum with $\theta = 135°$, since it contains the same multiplicity information as the attached proton test (APT) experiment with higher sensitivity. Comparison of the DEPT135 with a normal $^{13}$C spectrum will permit assignment of quaternary carbons, as they will be suppressed in all DEPT spectra. The DEPT135 spectrum of abietic acid is shown in Figure 3(d). Although the methyne and methyl signals are of the same phase, the intensity and chemical shift information will often sufficient to distinguish methyls (more intense, more upfield) from methylenes.

### 2.7 Nuclear Relaxation in Carbon-13 Nuclear Magnetic Resonance Spectroscopy

Magnetization is observed in the NMR experiment through application of an rf pulse. This pulse forces the net magnetization vector, $M_z$, to precess about this applied field, toward the observable transverse plane. At the end of this pulse, the magnetization vectors begin the relaxation process through the exchange of excess energy in the spin system with other spins and with the local surroundings to return to equilibrium. The process of energy exchange with other spins is called spin–spin relaxation, $T_2$. Loss of energy to the surrounding structural environment is called spin-lattice relaxation, $T_1$. $T_2$ relaxation causes a dephasing of spin components of $M_z$ in the $x,y$ plane. In contrast, $T_1$ relaxation is the mechanism through which the spin system returns to equilibrium.

Relaxation processes occur as a result of the interaction of the magnetization vectors with oscillating local fields in the molecule created by molecular motion of the proper frequency. As the rates of molecular motion, lattice vibrations, molecular tumbling, and reorientation, change, both $T_1$ and $T_2$ will change. For small molecules, $T_1$ can be long, seconds to minutes in length, while polymers typically exhibit relaxation times in the 0.1 to 1 second that grow longer, after passing through a minimum, with decreased molecular motion as temperature is lowered. Small molecule $T_2$s are typically close to their $T_1$ values in a primarily dipolar relaxation spin system, and decrease to a minimum value as molecular size increases and molecular motion slows. The rate of molecular motion is important, represented by the molecular correlation time, $\tau_C$, as are the number of directly attached protons. In all systems, $T_2 \leq T_1$, since the magnetization cannot be at equilibrium if there is still a transverse component.

The importance of relaxation in spectroscopic analysis is the fact that it limits the ability to acquire resolved NMR spectra in as short a time as possible. $T_1$ relaxation creates a lower limit on the time delay between successive scans in the pulse NMR experiment to obtain quantitative results. Delay times of 5 $T_1$s are necessary for spin systems to return to full equilibrium, substantially increasing signal acquisition times as $T_1$ values lengthen. $T_2$ limits the resolution in a spectrum by causing a line broadening as $T_2$ decreases.

Relaxation time experiments in solution have traditionally focused on the measurement of $T_1$ values, as these values are diagnostic of structure and dynamics. Since relaxation times largely reflect molecular motion, studies are usually undertaken to study the type and rate of motions and factors that affect these parameters, such as associative phenomena. The rate and strength of intermolecular associative complexes have an effect on isotropic motion and can be examined through $T_1$ measurements. Relaxation studies can be used to distinguish different modes of motion or segmental mobility in a molecule, reflected in different $T_1$ values for carbon atoms in the same molecule. For small rigid molecules, $T_1$ values can be used to distinguish the number of protons attached to a carbon, since for rigid molecules, correlation times determined at all carbon positions are the same, and differences in $T_1$ reflect only differences in the number of directly attached protons. Determination of
where \( N \) values is also necessary to establish quantitative conditions for analytical measurements. The longest \( T_1 \) value in a spectrum is used to set the delay period between scans in quantitative experiments, five times \( T_1 \), to allow every part of the spin system to return to equilibrium. \( T_1 \) measurements can be used to determine \( T_C \), an important parameter for conformational analysis using molecular modeling. The dynamics of a molecular system must be known to use NOE experiments effectively for distance determinations. \( T_2 \) relaxation times are of value when designing new NMR experiments, since spin dephasing limits the length of time a pulse sequence can be carried out before observable magnetization is gone and cannot be refocused.

2.7.1 Spin-lattice (\( T_1 \)) Relaxation

Spin-lattice relaxation is most efficient at motional frequencies close to the Larmor frequency of the nucleus being observed and is thus a field-dependent parameter. Contributions to \( T_1 \) result from a series of mechanisms, as shown in Equation (21):

\[
\frac{1}{T_1} = \frac{1}{T_{1(DD)}} + \frac{1}{T_{1(SR)}} + \frac{1}{T_{1(SC)}} + \frac{1}{T_{1(CSA)}} + \frac{1}{T_{1(ES)}} \tag{21}
\]

where \( T_{1(DD)} \) is the component due to heteronuclear dipole–dipole interactions, \( T_{1(SR)} \) is from spin rotation, \( T_{1(SC)} \) from scalar couplings, \( T_{1(CSA)} \) from chemical shift anisotropy (CSA), and \( T_{1(ES)} \) from unpaired-electron–spin interactions. In the absence of unpaired electrons in the molecule or paramagnetic impurities in the sample, the predominant relaxation mechanism in \( ^{13}\text{C} \) NMR of organic molecules is through heteronuclear dipole–dipole interactions between carbon atoms and directly bonded protons or those in close spatial proximity. Molecular tumbling and C–H bond rotation reorient the spin dipoles, creating local magnetic fields that constantly fluctuate, providing a pathway for relaxation. Oscillating local fields induce nuclear spin transitions if there are molecular motions with frequency components near \( \nu_0 \) of the observed nucleus. \( T_{1(DD)} \) for a molecule in dilute solution with isotropic motion in the extreme narrowing limit \( (w_H + w_C)T_C \ll 1 \) can be simplified to Equation (22):

\[
\frac{1}{T_{1(DD)}} = N \left( \frac{h}{2\pi} \right)^2 \gamma_C^2 \gamma_H^2 v_C^2 v_H^2 (I_{CH}^n)^2 T_C \tag{22}
\]

where \( N \) is the number of directly bonded \(^1\text{H} \) nuclei, \( \gamma_C \) is the gyromagnetic ratio of carbon, \( \gamma_H \) is the gyromagnetic ratio of hydrogen, \( I_{CH}^n \) is the internuclear distance and \( T_C \) is the molecular correlation time. While this equation does not show the field dependence of \( T_1 \), it is reduced from an equation containing spectral density functions which contain \( w_C \) and \( w_H \) terms that approach unity with rapid isotropic motion. Using this equation, a methylene group with \( \tau_C = 10^{-11} \) s, would have a \( T_{1(DD)} \) of \( \sim 1.5 \) s neglecting neighbor and intermolecular effects. This component of spin-lattice relaxation is the basis of NOE measurements discussed in section 2.5 and the experimentally determined NOE factor can be used to determine the contribution of dipole–dipole interactions to the overall \( T_1 \). A full NOE indicates that dipole relaxation, and thus \( T_{1(DD)} \), is the only contributor to observed relaxation behavior. Incomplete NOE reveals contributions from other relaxation mechanisms.

Molecules or portions of a molecule that have an angular velocity produce local magnetic fields due to the reorientation of the electrons contained in chemical bonds. This spin rotation contributes to relaxation as \( T_{1(SR)} \) and is described in Equation (23):

\[
\frac{1}{T_{1(SR)}} = \left\{ \frac{2kT}{3(\hbar/2\pi)^2} J_m (C_1^2 + C_2^2) \right\} \tau_{SR} \tag{23}
\]

where \( J_m \) is the moment of inertia relative to axis \( m \), \( C_1 \) and \( C_2 \) are spin rotation constants perpendicular and parallel to the symmetry axis of the molecule or functional group, and \( \tau_{SR} \) is the correlation time for spin rotation or angular momentum. In typical systems, perturbation of angular velocity occurs at rates making this mechanism inefficient in liquids. Contributions from spin rotation can be significant for unprotonated carbons with modest dipole relaxation components, or pendant alkyl groups with motional velocities on the order of \(^{13}\text{C} \) Larmor frequencies. Since angular velocity increases with temperature, contributions to relaxation will also increase and an examination of the temperature dependence of \( T_1 \) will confirm the presence of \( T_{1(SR)} \) mechanisms.

Coupling of \(^{13}\text{C} \) nuclei to other atoms provides a potential mechanism for relaxation if that nucleus has a nonzero spin quantum number. If the bonded nucleus relaxes rapidly, a condition found with many common quadrupolar nuclei, oscillating local fields are created which provide a pathway for \(^{13}\text{C} \) relaxation. The scalar relaxation contribution is defined in Equation (24):

\[
\frac{1}{T_{1(SC)}} = \frac{8\pi^2 J^2}{3S(S+1)} \frac{\tau_{SC}}{1 + (w_S - w_C)^2 \tau_{SC}^2} \tag{24}
\]

where \( J \) is the scalar coupling between the carbon atom and nucleus \( S \), \( S \) is the spin quantum number of nucleus \( S \), \( \tau_{SC} \) is the relaxation time of nucleus \( S \), and \( w_S \) is the Larmor frequency of nucleus \( S \). In typical \(^{13}\text{C} \) spectra, this mechanism does not significantly contribute to \( T_1 \) relaxation, but can be the dominant factor in \( T_2 \). This mechanism is field-dependent, since its mathematical description contains the term \( (w_S - w_C) \). As these terms are also in the denominator of Equation (24), the second term is small. Only in the event of a very large coupling...
do scalar coupling mechanisms contribute to spin-lattice relaxation.

As discussed in section 2.4, the chemical shift of a carbon atom is described by a tensor which has some orientation within the molecular framework. The $^{13}$C chemical shielding is thus dependent on the orientation of the molecule to $H_0$, as well as the size of $H_0$, and becomes a significant contributor to relaxation at larger magnetic fields. Rapid isotropic motion averages the chemical shift to an isotropic value, but the anisotropic components create an oscillating field due to the rapid reorientation of the chemical shift tensor with respect to $H_0$. This relaxation rate is described in Equation (25):

$$\frac{1}{T_{1(CSA)}} = \frac{2}{15} \gamma_C^2 H_0^2 (\sigma_1 - \sigma_\perp)^2 \tau_C$$

where $\sigma_1$ and $\sigma_\perp$ are the components of the CSA which are oriented parallel and perpendicular to $H_0$. Contributions to relaxation from the CSA will depend on the size and shape of the anisotropy, as well as $\tau_C$.

Unpaired electrons are an effective contributor to $T_1$ and $T_2$ relaxation. Electrons can interact with $^{13}$C nuclei either through dipole–dipole couplings or through a scalar electron–nucleus coupling. These contributors to relaxation rates are defined in Equations (26) and (27):

$$\frac{1}{T_{1(ES)}} = \frac{2S(S + 1)\gamma_e^2}{15\gamma_C^2} \frac{3\tau_{C1}}{1 + w_c^2 \tau_{C1}} + \frac{7\tau_{C2}}{1 + w_c^2 \tau_{C2}}$$

$$\frac{1}{T_{1(ES)}} = \frac{8\pi^2 A^2}{3} \frac{\tau_{e2}}{S(S + 1)} \frac{\tau_{C2}}{1 + (w_C - w_e)^2 \tau_{e2}^2}$$

where $\gamma_S$ is the magnetogyric ratio for an electron, $w_e$ is the resonance frequency of the electron, $A$ is the hyperfine spin nuclear coupling constant, and $\tau_{C1}$ and $\tau_{C2}$ are correlation times consisting of contributions from $\tau_C$, $\tau_{C1}$ and $\tau_{e2}$, the electron relaxation times and $\tau_m$, the lifetime of the complex contributing the unpaired electron. The dipole mechanism in Equation (26) only requires some interaction between the unpaired electron and the molecule being observed, while the scalar mechanism is only active when the unpaired spin can be delocalized through bonding. Since electrons have very large magnetic moments, couplings between them and surrounding nuclei are greater than nuclear dipole couplings and the presence of unpaired electrons can dominate both spin-lattice and spin–spin relaxation rates. An advantage to the presence of unpaired spins is the shorter $T_1$ relaxation times found for $^{13}$C spins, permitting shorter delay times between successive scans. Paramagnetic relaxation agents added to shorten $T_1$ s can also quench NOEs, making data more quantitative at the cost of sensitivity enhancement. Unpaired spins shorten $T_2$, effectively broadening spectral resonances.

$T_1$ values are measured using an inversion-recovery sequence. In this experiment, shown in Figure 9(b), the net magnetization is inverted with a nonselective $\pi$ pulse followed by a delay, $\tau$, to allow relaxation to occur. This is followed by a $\pi/2$ pulse and acquisition of the $^{13}$C NMR spectrum. A series of spectra are collected while changing the delay between pulses to cover a range from 0.1 $T_1$ to 5 $T_1$. A spectrum with a very short $\tau$ will have all lines inverted in phase relative to one with a long $\tau$ value. The integrated peak areas or intensities are plotted as a function of $\tau$ to produce a plot like that shown in Figure 10. This curve is fitted to an exponential function of the type shown in Equation (28):

$$I = I_0(1 - Ae^{(-\tau/T_1)})$$

where $I$ is the measured peak area or intensity, $I_0$ is the equilibrium magnetization value, $A$ is a constant and $\tau$ is the delay between pulses. The data are fitted to this equation iteratively to obtain $T_1$. Other methods for measurement of $T_1$ include saturation–recovery, and progressive-saturation. These methods examine the recovery of magnetization, but through either saturation of the spins with a delay before observation or attenuation of the observed magnetization using a multiple-pulse sequence. The inversion-recovery method is the most commonly used sequence, but the progressive-saturation method is advantageous for measuring long $T_1$ values.

### 2.7.2 Spin–Spin ($T_2$) Relaxation

Spin–spin relaxation is a function of molecular motion and the inhomogeneity of the external magnetic field. In

![Figure 10](image_url)

**Figure 10** Plot of $^{13}$C peak intensities as a function of $\tau$ acquired using the pulse sequence shown in Figure 9 and fit to Equation (28) to determine $T_1$ using the inversion recovery method.
the latter case, molecules moving through the magnetic field experience slightly different $H_0$ fields and thus precess with slightly different $\nu_0$ values. This is minimized, but not eliminated, by adjusting the magnetic field to make it homogeneous across the sample. As a result, spin coherence is lost and the magnetization dephases in the transverse plane. Unlike $T_1$, $T_2$ is a result of energy exchange between spins rather than a loss of energy to the molecular lattice. In the motional narrowing limit, $(\nu_0 + \nu_c)T_C \ll 1$, $T_2 = T_1$ as in Equation (22). $T_2$ relaxation is also sensitive to the same mechanisms as discussed in the previous section, particularly when scalar couplings to quadrupolar nuclei or couplings to unpaired electrons are present.

Spectral line widths are determined by $T_2$ values and spectrometer magnetic-field inhomogeneities shown by Equations (29) and (30):\(^{(21,64)}\)

$$\Delta \nu_{1/2} = \frac{1}{\pi T_2}$$

$$\frac{1}{T_2} = \frac{\gamma \Delta B_0}{2} + \frac{1}{T_2}$$

where $\Delta \nu_{1/2}$ is the full width at half height of the spectral resonance. $T_2^*$ is the sum of magnetic-field inhomogeneity effects, $\gamma \Delta B_0$, and $T_2$ due to spin–spin interactions. For typical NMR spectrometers with small molecules in the extreme-narrowing region of molecular motion, the resonance line width is dominated by field inhomogeneities. In this case, spin–echo experiments are used to determine intrinsic $T_2$ values. Larger molecules and polymers, having slower molecular motions that shorten $T_2$, exhibit broadened lines resulting in $\Delta \nu_{1/2} \sim 1/\pi T_2$. In molecules with quadrupolar nuclei or unpaired spins, $T_2$ decreases and broadens spectral resonances.

Measurement of $T_2$ is carried out with the Carr–Purcell–Meiboom–Gill (CPMG) pulse sequence.\(^{(167,168)}\) This experiment begins with a 90° pulse followed by a series of 180° refocusing pulses, spaced by an appropriate interval. During the delay, both chemical-shift and spin–spin interactions occur. The 180° pulse refocuses the chemical-shift process and, at an appropriate time, the magnetization has been refocused. Acquisition of an FID at this point will contain a normal spectrum, but the peaks will be attenuated due to $T_2$ relaxation effects because the dephasing due to $T_2$ is not refocused in this experiment. A series of spectra are collected, each with an increasing number of echo pulses and delays. Peak intensities will exponentially decay and can be fitted to Equation (31):\(^{(21)}\)

$$I_t = I_0 e^{-t/T_1}$$

with the same connotations as mentioned for $T_1$ analysis.

### 2.8 Multidimensional Carbon-13 Nuclear Magnetic Resonance Experiments

With the development of sophisticated computers and electronics capable of acquiring and processing large amounts of spectral data, multidimensional NMR methods have become the mainstay of the chemist wishing to identify an unknown material, determine physical parameters such as scalar couplings or study molecular conformations and associative phenomena. First proposed in 1971,\(^{(169)}\) the seminal work of Ernst et al.\(^{(170,171)}\) made 2-D NMR a reality and heralded a new era in NMR spectroscopy. Multidimensional NMR methods contain information on spin systems, i.e. which nuclei are scalar coupled to each other through scalar or dipolar interactions or through chemical-exchange pathways. Since the initial development of these methods, 2-D and higher-order NMR experiments have become pervasive tools in studying the molecular structure of organic materials, especially in the area of proteins, where information about the 3-D structure can be obtained through NOE and scalar coupling experiments. As in all NMR methods though, direct observation of $^{13}$C signals reduces the sensitivity of any experiment and most of the recent developments are for inverse or indirect detection experiments where the spectrum is acquired through the $^1$H signal. Rather than observe the effect of C–H couplings on the carbon signals, it has become much easier and quicker to observe the same effect on the proton signals. Consequently, there are only a few 2-D experiments for which the $^{13}$C signal is measured and these are discussed below. Several excellent reference volumes provide a detailed description of multidimensional NMR and its implementation for structural determination and the study of dynamic phenomena.\(^{(60,172,173)}\)

#### 2.8.1 Description of Multidimensional Nuclear Magnetic Resonance Spectroscopy

A standard chemical-shift experiment comprises two basic components, preparation and detection of the NMR signal. The preparation step in $^{13}$C-NMR generates $^{13}$C observable magnetization with an rf pulse while saturating the $^1$H spins with heteronuclear decoupling. Detection involves turning on the receiver and observing the voltage induced in the sample probe coil. More sophisticated techniques, such as INEPT, may have a mixing period in which spins exchange information through scalar or dipolar couplings. The detection period where the NMR signal is observed as a function of time is called the acquisition period, or $T_2$. Multidimensional techniques have a second time period, $T_1$, which is known as the evolution time. This second evolution period is for spin systems to evolve under the influence of scalar couplings, dipolar oscillations creating cross-relaxation pathways,
chemical dynamics or exchange as a function of the $T_1$ time increment. A 2-D NMR spectrum is created by acquiring a series of 1-D FIDs (64 to 512) spaced by a constant increment of the evolution time, $T_1$. The result is an array of FIDs, each in the time variable $T_2$, spaced uniformly over the total $T_1$ period. A double FT, once along each axis of the array, produces a 2-D spectrum with dimensions in frequency units $f_2$ and $f_1$. This process is shown schematically in Figure 11. For 2-D spectra where $^{13}$C is the detected nucleus, $f_2$ is the $^{13}$C chemical-shift dimension and $f_1$ is either the chemical shift of some other nucleus, the heteronuclear coupling dimension or the double-quantum-frequency dimension. A pulse program for a $^{13}$C–$^1$H HETCOR experiment is shown in Figure 9(d). The basic unit of many 2-D and higher-order NMR experiments is the polarization transfer sequence discussed earlier and shown in Figure 9(c). The appropriate selection of pulse sequences establishes the type of pathway or spin evolution that is to occur in $T_1$.

2.8.2 Two-dimensional Nuclear Magnetic Resonance

There are three primary 2-D NMR experiments for the study of $^{13}$C nuclei, not including the inverse, $^1$H detected analogs of each. $^{13}$C–$^1$H scalar couplings and carbon multiplicities can be observed through the 2-D J-resolved technique, which has $^{13}$C chemical shifts along one axis and $^{13}$C–$^1$H $^1$J$_{CH}$ coupling multiplets in the second dimension. HETCOR experiments establish connectivities between scalar coupled carbon and hydrogen atoms in a molecule. Carbon–carbon connectivities can be established through 2-D INADEQUATE spectroscopy, a difficult but rewarding technique for study of the carbon skeleton in a molecule.

Determination of $^1$J$_{CH}$ scalar couplings is valuable in structural analysis for the assignment of multiplicities of carbon atoms, the relative $s$ character in carbon hybridization and the electron-withdrawing nature of substituents. The J-resolved 2-D spectrum separates $^{13}$C chemical shifts from $^1$J$_{CH}$ scalar couplings, while suppressing $^1$H chemical shifts and homonuclear couplings. This simple experiment uses a spin echo to refocus $^{13}$C chemical-shift information, while allowing $^{13}$C–$^1$H scalar couplings to modulate the echo in the evolution period. The result is a 2-D spectrum with $^{13}$C chemical shifts on the $f_2$ axis and C–H coupling information in the $f_1$ dimension. From studying the $f_1$ slice at each $^{13}$C resonance, the multiplicity and $^1$J$_{CH}$ can be determined for each signal. Analogous to acquiring a 1-D $^{13}$C spectrum with the decoupler off during acquisition, this method has the advantage of removing the overlap found in 1-D spectra, such as the spectrum of abietic acid shown in Figure 3(a).

Assignment of spectral resonances is a crucial step in the process of structure determination. If assignments of $^{13}$C or $^1$H signals are known, then HETCOR is used to establish the assignment of the coupled nucleus. The HETCOR experiment transfers information generated from one-bond scalar $^1$J$_{CH}$ couplings with a polarization-transfer sequence to observe $^{13}$C resonances. The time evolution of the $^1$J$_{CH}$ coupling introduces a phase modulation of the detected $^{13}$C signals and, when Fourier transformed, yields a $^1$H dimension in the 2-D spectrum. The $^{13}$C–$^1$H HETCOR spectrum of abietic acid is shown in Figure 12. The horizontal axis is the $^{13}$C chemical-shift dimension and the vertical is the $^1$H dimension. Bonding partners are seen as peaks where the $^{13}$C and $^1$H frequencies intersect. The solid lines in the spectrum trace several of the correlations, for example, the methyl carbon resonance at 14 ppm is seen to correlate with the proton signal at 0.8 ppm.

Structural analysis requires the unambiguous establishment of carbon–carbon connectivities, identification of functional-group arrangements and the presence of heteronuclei in the carbon skeleton. A difficult but rewarding technique for this purpose is the INADEQUATE. In this experiment, $^{13}$C–$^{13}$C connectivities are determined by allowing spins to precess, while evolving only under the influence of $^1$J$_{CC}$ couplings. The resulting spectrum, an example of which is shown in Figure 13, contains $^{13}$C chemical shifts along one axis and the double-quantum frequency (the sum of the chemical shifts of the coupled spins) axis along the second dimension. If two
spins are coupled, their resonances, at \( v_{Ca} \) and \( v_{Cb} \), each have a correlation peak in the \( f_1 \) dimension at \((v_{Ca} + v_{Cb})\), shown by solid lines in the spectrum of Figure 13 for several spin pairs. Each correlation peak is split into doublets spaced by \( J_{CC} \). The carbon skeleton can be followed by “walking” through the connectivity pathways shown in the spectrum. Any breaks in the correlation path indicate either insertion of a heteroatom in the skeleton or the termination of a structure. Since this experiment suppresses the central \( ^{13}\text{C} \) resonance while the \( ^{13}\text{C} - ^{13}\text{C} \) satellites are observed, signals which are only 0.55% of the central \( ^{13}\text{C} \) signal, it is a difficult experiment that requires a high-field NMR spectrometer and maximum sample concentrations. This technique is difficult and is often replaced by a combination of \(^1H\) inverse experiments.

Development of \(^1\text{H}\) multidimensional NMR methods has surpassed that of \(^{13}\text{C}-\text{NMR}\) for many reasons. Sensitivity of the \(^1\text{H}\) experiment is the first advantage, coupled with shorter relaxation times. Spectra of sub-microgram samples can be obtained in minutes and, with the application of field gradients, 2-D experiments can be acquired in under 30 minutes. NMR probes in the inverse configuration are used to acquire HETCOR spectra with \(^1\text{H}\) rather than \(^{13}\text{C}\) detection, with significant time savings,\(^{179}-^{182}\) In many studies of molecular structure, only a 1-D \(^{13}\text{C}\) spectrum is acquired, with all other information derived through inverse experiments. Even the 2-D INADEQUATE for determining \(^{13}\text{C}-^{13}\text{C}\) connectivities has a \(^1\text{H}\) detected version, 2-D INEPT–INADEQUATE\(^{183}\) that takes advantage of heteronuclear polarization transfer to transfer carbon skeleton information to attached protons. Of course, the drawback to these experiments is that quaternary carbons may be overlooked since polarization-transfer methods do not detect them.

3 CURRENT PERSPECTIVE AND FUTURE DEVELOPMENT

\(^{13}\text{C}\)-NMR spectroscopy is and will continue to be one of the most valuable tools for the analysis of organic molecules. It is pervasive throughout the chemical literature in most areas of chemistry and biochemistry and is routinely used for the structural analysis of organic molecules, the study of polymer structure and dynamics, analysis of molecular conformation in biopolymers, elucidation of reaction mechanisms or biosynthetic pathways. Applications have grown substantially in the last two decades and will continue to do so with the further refinement of NMR instrumentation and the development of polarization-transfer techniques for improved sensitivity and spectral-editing capabilities. NMR spectroscopy is a routine analytical tool for the student as well as the professional scientist and access to instrumentation is widespread.

The simulation and prediction of NMR spectra will continue to develop. There is still much to be understood about the chemical shift and how best to calculate meaningful tensor values. An understanding of the chemical shift and its orientation in the molecular framework are important parameters in both structural and conformational analysis. Along with the fundamental principles defining the chemical shift, significant developments in the area of molecular-modeling software have simplified, and will continue to simplify, the task of solving...
Schroedinger’s equation for molecular energies. Dramatic improvements in the speed of computer hardware for doing such calculations puts the challenge of doing ab initio calculations within the grasp of those with access to only desktop PC systems.

While suffering from low inherent sensitivity compared to $^1$H, the spectral dispersion of $^{13}$C-NMR provides significantly greater resolution of functional groups than does $^1$H NMR. To circumvent low sensitivity, larger magnetic-field strengths are being made available at a rapid rate. Magnets with field strengths of 18 tesla are commercially available with $^{13}$C resonance frequencies at 200 MHz. This increase in field strength continually enhances the utility of $^{13}$C-NMR measurements, since the net observable magnetization scales with $H_0$. At these higher fields, it may be possible to learn more about the CSA of $^{13}$C nuclei and the orientation of this anisotropy to the molecular framework. Larger magnetic fields can produce preferential orientation of molecules, reintroducing anisotropic motion and line broadening. Improved resolution may also permit the observation of conformational and sequential effects in polymers over a larger distance than currently available. Refinement of statistical models for reactivity and catalyst activity will result.

However, one cannot ignore the shortcomings of $^{13}$C-NMR as a method for quantitative analysis. Even with great care in selection of parameters, quenching of NOE and with an understanding of relaxation in the system of interest, one may achieve a relative precision rate of one percent, and worse at lower component levels. Under highly quantitative conditions, analysis times will be very long. In cases of very low component levels, the technique may not have adequate sensitivity to observe trace materials. While $^{13}$C-NMR may never be the most precise analytical technique, it finds substantial use as a qualitative technique and will most likely remain a powerful identifier of functional groups in a sample, serving as a reference method for other analytical techniques. The cost of instrumentation, up to several million dollars for state-of-the-art 800 MHz systems, makes it prohibitive to place an NMR in plant operations. Using NMR to calibrate other methods, such as infrared and Raman spectroscopy, does however allow NMR to be of use in commercial operations.

Chemical Shifts in Nuclear Magnetic Resonance

Scott E. Van Bramer
Widener University, Chester, USA

1 Introduction

1.1 Definition of Chemical Shift

The chemical shift, \( \delta \), in NMR spectroscopy is defined in Equation (1):

\[
\delta = \frac{v_{\text{sample}} - v_{\text{reference}}}{v_{\text{reference}}} \times 10^6 \text{ ppm}
\]

The reference frequency, \( v_{\text{reference}} \), is measured by adding a small amount of the reference compound to the sample. The signal frequency, \( v_{\text{sample}} \), is the Larmor frequency for the nucleus of interest. Equation (1) is frequently written using the spectrometer frequency, \( v_{\text{spectrometer}} \), as shown in Equation (2):

\[
\delta = \frac{v_{\text{sample}} - v_{\text{reference}}}{v_{\text{spectrometer}}} \times 10^6 \text{ ppm}
\]

The strength of the instrument’s static magnetic field determines \( v_{\text{spectrometer}} \). Because this is a fixed value, the chemical shift axis is readily calculated. In liquid \(^{13}\text{C}\) and \(^1\text{H}\) NMR spectra the difference between Equations (1) and (2) is insignificant.

1.2 Chemical Shift Reference

Tetramethylsilane (TMS) is used as the primary reference for \(^1\text{H}\)- and \(^{13}\text{C}\)-NMR. The spectrum is plotted with TMS at 0 ppm, on the right. Increasing chemical shift, \( \delta \) in parts per million, is plotted from right to left. Increasing chemical shift also corresponds to increasing frequency, decreasing magnetic field strength,

TMS is the primary chemical shift standard and should be used whenever possible. Samples in polar solvents and many older literature values are referenced to a secondary standard. This is most common for $^{13}$C data in the older literature. Table 1, from Levy and Cargioli, lists the chemical shifts of several other compounds that have been used as $^{13}$C NMR standards.

1.3 Solvent Peaks

Carbon-13 NMR spectra are typically acquired by dissolving a sample in a suitable solvent. Table 2, from Breitmaier and Voelter, gives the chemical shift, splitting patterns, and coupling constants for the most common NMR solvents. The chemical shift for many solvents is concentration-dependent and may change when a solute is added. As a result, the solvent is not an appropriate chemical shift reference for NMR.

1.4 Theory

NMR is such a powerful tool for structural identification because the chemical shift depends upon the electronic

Figure 1  Carbon-13 chemical shift correlation. (Reproduced by Permission of Wiley–VCH and E. Breitmaier from E. Breitmaier, W. Voelter, Carbon-13 NMR Spectroscopy, Methods and Applications in Organic Chemistry and Biochemistry, VCH, Weinheim, Germany, 1990.)
environment surrounding each atom in a molecule. When a sample is placed in the spectrometer, the magnetic field causes the electron cloud surrounding a nucleus to circulate. This circulating current produces a magnetic field that opposes the magnetic field of the spectrometer. The result is a shielding of the nucleus from the applied magnetic field. Different chemical shifts are caused by different amounts of shielding. One example of this is caused by highly electronegative elements. When an electronegative element is nearby, it reduces the electron density surrounding a nucleus. This deshields the nucleus so that the NMR signal is observed with a large chemical shift. The chemical shift of methane is 0.13 ppm but the chemical shift of chloromethane is 3.05 ppm. Another example of this shielding is the ring current observed in aromatic compounds. This ring current is caused by the free circulation of electrons around the aromatic ring. Depending upon the geometry of the molecule, these induced currents may result in either shielding or deshielding of nuclei.

2 CARBON-13 CHEMICAL SHIFT

2.1 Correlation Table

Carbon-13 chemical shifts are predicted using additivity rules to account for the deshielding caused by various functional groups. Figure 1 is a correlation table, based upon data from Breitmaier and Voelter, which shows the typical $^{13}$C chemical shift range for observing various functional groups. This figure is a useful starting point, but additivity rules are needed for more precise estimates of the chemical shift.

2.2 Alkanes

2.2.1 Grant and Paul Rule for Linear Alkanes

Grant and Paul developed Equation (3) for calculating the chemical shift of linear alkanes:

$$\delta = -2.6 + 9.12n_a + 9.38n_\beta - 2.53n_\gamma + 0.37n_5 + 0.17n_6$$  \hspace{1cm} (3)

In Equation (3) $\delta$ is the calculated $^{13}$C chemical shift; $-2.6$ is the $^{13}$C chemical shift for methane; $n_a$ is the number of $\alpha$-carbons, one bond removed from the carbon of interest; $n_\beta$ is the number of $\beta$-carbons, two bonds removed from the carbon of interest; $n_\gamma$ is the number of $\gamma$-carbons, three bonds removed from the carbon of interest; $n_5$ is the number of $\delta$-carbons, four bonds removed from the carbon of interest; and $n_6$ is the number of $\epsilon$-carbons, five bonds removed from the carbon of interest. This version of the Grant and Paul rule was developed using linear alkanes up to $n$-decane. The equation fits the 30 observed carbons in this data set with a standard deviation of ±0.21 ppm.

In Table 3, the Grant and Paul rule for linear alkanes is used to calculate the $^{13}$C chemical shift for $n$-pentane (109-66-0) (I). The chemical shifts calculated from Equation (3) very closely match the experimental data given by Pretsch et al.

2.2.2 Grant and Paul Rule for Branched Alkanes

The version of the Grant and Paul rule given in Equation (3) was developed for linear alkanes. If it is used to calculate the chemical shift for carbons in branched alkanes, the error increases significantly. To compensate for this, Grant and Paul developed a second equation that includes correction terms for branched alkanes. This equation was developed by fitting both the linear alkanes used for Equation (3) and branched alkanes with up to six carbons. The Grant and Paul rule for branched alkanes is given in Equation (4):

$$\delta = -2.6 + 9.09n_a + 9.40n_\beta - 2.49n_\gamma + 0.31n_5 + 0.11n_6 + \sum A$$ \hspace{1cm} (4)

The coefficients and the variables in Equation (4) are almost identical to Equation (3). As with Equation (3) $\delta$ is the calculated $^{13}$C chemical shift; $-2.6$ is the $^{13}$C chemical shift for methane; $n_a$ is the number of $\alpha$-carbons, one bond removed from the carbon of interest; $n_\beta$ is the number of $\beta$-carbons, two bonds removed from the carbon of interest; $n_\gamma$ is the number of $\gamma$-carbons, three bonds removed from the carbon of interest; $n_5$ is the number of $\delta$-carbons, four bonds removed from the carbon of interest; and $n_6$ is the number of $\epsilon$-carbons, five bonds removed from the carbon of interest. Although the coefficients for Equation (4) are slightly different from those of Equation (3), the most significant difference in

Equation (4) is term A. The values for A, given in Table 4, are added for each attached carbon to compensate for branching. Grant and Paul found that the calculated chemical shift using Equation (4) and the corrective terms in Table 4 predicted the measured value for 53 observations of linear and branched alkanes in their data set with a standard deviation of ±0.3 ppm.

Table 5 shows the calculations for the $^{13}$C chemical shifts in 2,2,4-trimethylhexane (16747-26-5) (2) using the Grant and Paul rule for branched alkanes. For comparison, the results of the Grant and Paul rule for linear alkanes and experimental data from Lindeman and Adams are also shown.

### 2.2.3 Lindeman and Adams Rule for Alkanes

A different method to calculate the chemical shift of alkanes was developed by Lindeman and Adams. The Lindeman and Adams rule was developed using all paraffin isomers through $C_6$ and 24 of the possible $C_9$ isomers. Lindeman and Adams compared their results with the Grant and Paul rules. The Grant and Paul rule for linear alkanes gave a standard error of ±2.0 ppm with the data set of 59 compounds used by Lindeman and Adams. Using the modified Grant and Paul rule for branched alkanes reduced the standard error to ±1.4 ppm. The Lindeman and Adams rule gave a standard error of ±0.79 ppm. For primary and secondary carbon atoms, all of the rules work well. The Lindeman and Adams rule, however, works better for the tertiary and quaternary carbon atoms in this data set. The authors note that the Lindeman and Adams rule does not work well for highly branched compounds.

The Lindeman and Adams rule is given in Equation (5):

\[
\delta_c(k) = B_S + \sum D_M A_{SM} + \gamma_S N_{k3} + \Delta_S N_{k4} \quad (5)
\]

The values for $B_S$, $A_{SM}$, $\gamma_S$ and $\Delta_S$ are given in Table 6; $\delta_c(k)$ is the calculated chemical shift of carbon $k$; $S$ is the number of carbons attached to carbon $k$; the value for $B_S$ is given in Table 6 for primary, secondary, tertiary
experimental shift

calculated shift using the Lindeman and Adams rule (Equation 5).

\[N_k\]

calculated shift using the Lindeman and Adams rule (Equation 5). To demonstrate the application of the Lindeman and Adams rule to a branched alkane, calculations are given in Table 7 for \(n\)-pentane (1). To demonstrate the application of the Lindeman and Adams rule to a branched alkane, calculations are given in Table 8 for 2,2,4-trimethylhexane (2). The results from the Lindeman and Adams rule and results from the appropriate Grant and Paul rule compare favorably with the experimental data from Pretsch et al.\(^{(4)}\) with the exception of C2 in 2,2,4-trimethylhexane. The Lindeman and Adams rule gives much better results for this highly branched carbon.

Table 7 gives \(^{13}\)C chemical shifts for selected linear and branched alkanes from Grant and Paul.\(^{(5)}\)

### 2.3 Substituted Alkanes

The Grant and Paul rules and the Lindeman and Adams rule are used to calculate the chemical shift of saturated alkanes. The addition of functional groups has a significant effect on the \(^{13}\)C chemical shift of any neighboring carbon atoms. The change in chemical shift, \(\Delta\), caused by substitution is consistent and additive. There are two common methods to account for the effect on the chemical shift of the alkane backbone.

The table below gives \(^{13}\)C chemical shifts for selected linear and branched alkanes from Grant and Paul.\(^{(5)}\)

### Table 8: Calculated \(^{13}\)C shifts for 2,2,4-trimethylhexane using the Lindeman and Adams rule (Equation 5)

2.3.1 Substituted n-Pentane

The change in the chemical shift of n-pentane caused by substitution at C1 is useful for calculating chemical shifts in substituted alkanes. Table 10 lists the change in the chemical shift for 13 different 1-substituted pentanes given by Abraham et al.\(^6\) The values in Table 10 are added to the chemical shift of the alkane backbone using the shift for C1 for the \(\alpha\)-carbon at the point of substitution, the shift for C2 for the \(\beta\)-carbon adjacent to the point of substitution, and continuing through the molecule. As shown in Table 10, the substituent effect drops off strongly after C3, the \(\gamma\)-carbon. 1-Hexanol (111-27-3) (3) is used in Table 11 as an example of how these values are used to calculate the chemical shift of a substituted alkane.
Table 13 Calculated $^{13}$C shifts for 1-bromobutane and 2-bromobutane using shifts for terminal and internal substitution from Wehrli et al.

2.3.2 Terminal and Internal Substitution

Because the effect of internal substitution is slightly different to the effect of terminal substitution, Wehrli et al. provide substituent effects for α, β, and γ carbons with either terminal or internal substitution. These values, given in Table 12, are based upon average chemical shifts for a number of alkanes, so they differ slightly from the n-pentane values. The $^{13}$C chemical shifts for 1-bromobutane (109-65-9) (4) and 2-bromobutane (78-76-2) (5) are calculated in Table 13. The experimental data for these compounds are from Aldrich.

2.4 Substituted Alkenes

The chemical shift of ethylene, 123.3 ppm, is used as the basis for calculating the $^{13}$C chemical shifts of alkene carbons using Equation (6):

$$\delta = 123.3\text{ ppm} + \sum A_{ki} + \sum A'_{ki} + \sum \text{correction} \quad (6)$$

The effect of substitution on the chemical shift of ethylene is given in Table 14 with data from Wehrli et al. The data used by Wehrli for acyclic alkenes are derived from Dorman et al., where the predicted chemical shift for acyclic alkenes has a standard error of ±0.9 ppm. The chemical shift calculated using Equation (6) and Table 14 is for the C$^\gamma$ carbon. Effects for α, β and γ are with substitution on the same side of the double bond; effects for α', β' and γ' are with substitution across the double bond; and the correction factors account for geometry across the double bond. Table 15 demonstrates the use of these data to calculate the $^{13}$C chemical shifts for 3-methyl-2-buten-1-ol (556-82-1) (6).

Table 14 Alkene chemical shifts, $\Delta\delta$, with α, β, and γ substitution at C$^\gamma$ for use with Equation (6). (Reproduced by permission of John Wiley & Sons Limited from F.W. Wehrli, A.P. Marchand, S. Wehrli, Interpretation of Carbon-13 NMR Spectra, 2nd edition, John Wiley & Sons, New York, 1988.)

2.5 Substituted Benzenes

Data for the $^{13}$C chemical shifts of monosubstituted benzene are given in Table 16. This listing from Silverstein and Webster is derived from a much more extensive compilation by Ewing. The values for the substituent effect, $\Delta\delta$, in Table 16 are used with Equation (7), where

(continued overleaf)
Pretsch et al. These values may be used with the additivity values given for alkanes, alkenes, and benzene to calculate the chemical shifts for many substituted cyclic compounds. Figure 2 provides a useful starting point but for more accurate calculations with these compounds other resources should be consulted.

3 PROTON CHEMICAL SHIFTS

Calculations of proton (1H) chemical shifts are usually less accurate than the calculations for 13C chemical shifts. Many of the rules given here result in a standard error of ±0.1 ppm for the set of compounds used to produce the rule. For compounds not included in the data set, errors of ±0.5 ppm are typical. In 1H-NMR, the substituent effects are frequently called Shoolery coefficients or deshielding values. Shoolery’s original listing of ten values in a Varian technical bulletin has been modified by many subsequent authors who optimized the coefficients with different sets of compounds. The first two methods given below are fairly general and easy to apply, but are the least accurate. The other methods provide improved accuracy for a smaller range of proton types. For the most accurate results, find the method that most closely matches the proton of interest.

3.1 Correlation Table

Figure 3 is a correlation table for proton chemical shifts using data from Breitmaier. This provides an overview of proton chemical shifts for various functional groups. The additivity rules provide shifts for additional functional groups and improved accuracy.

3.2 Substituted Alkanes

3.2.1 Friedrich Brief Proton Chemical Shifts

This method provides quick estimates for methyl (CH₃) and methylene (CH₂) protons. The appropriate value from Table 18 for each substituent on the carbon is added to calculate the proton chemical shift. For most common functional groups, the results are generally within ±0.5 ppm. Table 19 shows the proton chemical shift calculations for chloroethane (75-0-3).

3.2.2 Jeffreys Proton Chemical Shifts

This is another quick method to calculate the chemical shift of protons attached to a carbon atom. It is a more general method than the Friedrich brief proton method because it works for protons on any type of carbon. The deshielding values for various carbon substituents are given in Table 20. These values are added together to calculate the predicted chemical shift.
for the proton of interest. Results are generally within ±0.3 ppm; however, aldehyde protons give poor results. Table 21 gives the calculated chemical shifts for 3-methyl-2-butene-1-ol (6), with experimental data from Aldrich for comparison.

3.2.3 Friedrich Detailed Proton Chemical Shifts

This method uses a more extensive table of deshielding values to calculate more accurately the proton chemical shift. This method is only designed for use with methyl (CH$_3$) or methylene (CH$_2$) protons, but it should produce results within ±0.1 ppm of the experimental value. The chemical shift is calculated using Equation (8):

$$ \delta_{XCH_2Y} = 0.23 \text{ ppm} + \sigma_x + \sigma_y $$  

The deshielding values, $\sigma_x$ and $\sigma_y$, for substituent X and Y, respectively, are given in Table 22. Table 23 illustrates the use of this rule to calculate the proton chemical shifts of chloroethane.

3.2.4 Bell $\alpha$-Substituted Methylene Protons

This method is specifically for $\alpha$-substituted methylene protons. The deshielding values for this method were developed using a data set of 395 compounds containing two $\alpha$ functional groups. The method produces a standard error of ±0.14 ppm for this data set. For compounds with a single $\alpha$-substituent, the error increased to ±0.18 ppm. This method is very similar to the Friedich detailed proton method but the deshielding values were only optimized for methylene protons. As a result, the deshielding values are slightly different. For this rule, proton chemical shifts are calculated using Equation (9) for compounds $X$–CH$_2$–Y:

$$ \delta = 0.23 \text{ ppm} + \sum \alpha $$

</table>
The rule is applied to compounds with a deshielding value, \( \alpha \), given in Table 24. Based upon these values, the chemical shift for the protons on dichloromethane (75-09-2) is 0.23 + 2.48 + 2.48 = 5.19. This compares to the experimental value of 5.33 given by Pretsch et al.\(^4\).

### 3.2.5 Bell \( \alpha \)- and \( \beta \)-Substituted Methylene Protons\(^{15}\)

This method is based upon a data set containing 1007 compounds with methylene protons having one \( \alpha \)-substituent and one or more \( \beta \)-substituents. The standard error using Equation (10) and the deshielding values in Table 25 with the 1007 compounds in this data set was \( \pm 0.15 \) ppm.

\[
\delta = 1.20 \text{ ppm} + \sum_\alpha + \sum_\beta \quad (10)
\]

The rule is applied to compounds with \( \text{CH}_2 - \text{C} - \text{xyz} \), where \( w \) is the \( \alpha \)-substituent and \( x, y, \) and \( z \) are \( \beta \)-substituents.

Using this method to calculate the chemical shift for 1,2-dichloroethane (107-06-2) gives the proton chemical shift of 1.20 + 2.04 + 0.36 = 3.62. Pretsch et al.\(^4\) give an experimental value of 3.27 ppm.
